Hayes; and Rafael Molina; Ovarian Cancer: Daniel W. Chan, Chair; Robert C. Bast, Jr.; Ie-Ming Shih; Lori J. Sokoll; and György Sölétormos

BACKGROUND: Updated National Academy of Clinical Biochemistry (NACB) Laboratory Medicine Practice Guidelines for the use of tumor markers in the clinic have been developed.

METHODS: Published reports relevant to use of tumor markers for 5 cancer sites—testicular, prostate, colorectal, breast, and ovarian—were critically reviewed.

RESULTS: For testicular cancer, α-fetoprotein, human chorionic gonadotropin, and lactate dehydrogenase are recommended for diagnosis/case finding, staging, prognosis determination, recurrence detection, and therapy monitoring. α-Fetoprotein is also recommended for differential diagnosis of nonseminomatosus and seminomatosus germ cell tumors. Prostate-specific antigen (PSA) is not recommended for prostate cancer screening, but may be used for detecting disease recurrence and monitoring therapy. Free PSA measurement data are useful for distinguishing malignant from benign prostatic disease when total PSA is < 10 μg/L. In colorectal cancer, carcinoembryonic antigen is recommended (with some caveats) for prognosis determination, postoperative surveillance, and therapy monitoring in advanced disease. Fecal occult blood testing may be used for

CONCLUSIONS: Implementation of these recommendations should encourage optimal use of tumor markers.© 2008 American Association for Clinical Chemistry

We present here to clinical chemists, clinicians, and other practitioners of laboratory and clinical medicine the latest update of the National Academy of Clinical Biochemistry (NACB)25 Laboratory Medicine Practice Guidelines for the use of tumor markers in testicular, prostate, colorectal, breast, and ovarian cancers. These guidelines are intended to encourage more appropriate use of tumor marker tests by primary care physicians, hospital physicians and surgeons, specialist oncologists, and other health professionals.

Clinical practice guidelines are systematically developed statements intended to assist practitioners and screening asymptomatic adults 50 years or older. For breast cancer, estrogen and progesterone receptors are mandatory for predicting response to hormone therapy, human epidermal growth factor receptor-2 measurement is mandatory for predicting response to trastuzumab, and urokinase plasminogen activator/plasminogen activator inhibitor 1 may be used for determining prognosis in lymph node–negative patients. CA15-3/BR27–29 or carcinoembryonic antigen may be used for therapy monitoring in advanced disease. CA125 is recommended (with transvaginal ultrasound) for early detection of ovarian cancer in women at high risk for this disease. CA125 is also recommended for differential diagnosis of suspicious pelvic masses in postmenopausal women, as well as for detection of recurrence, monitoring of therapy, and determination of prognosis in women with ovarian cancer.

CONCLUSIONS: Implementation of these recommendations should encourage optimal use of tumor markers.

We present here to clinical chemists, clinicians, and other practitioners of laboratory and clinical medicine the latest update of the National Academy of Clinical Biochemistry (NACB)25 Laboratory Medicine Practice Guidelines for the use of tumor markers in testicular, prostate, colorectal, breast, and ovarian cancers. These guidelines are intended to encourage more appropriate use of tumor marker tests by primary care physicians, hospital physicians and surgeons, specialist oncologists, and other health professionals.

Clinical practice guidelines are systematically developed statements intended to assist practitioners and patients in making decisions about appropriate healthcare for specific clinical circumstances (1). An explanation of the methodology used when developing these guidelines is provided in an accompanying preamble (2). As might be expected, many of the NACB recommendations are similar to those made by other groups, as is made clear from the tabular comparisons presented for each malignancy (2). The disciplines of all authors and statements of conflicts of interest, declared according to NACB requirements, are provided in an online data supplement (Supplemental Data Disclosure Table that accompanies this Special Report at http://www.clinchem.org/content/vol54/issue12). The latter are also listed at the end of this manuscript. All comments received about these guidelines are also recorded in an online data supplement (Supplemental Data Comments Received Table), together with responses to these comments.

To prepare these guidelines, the literature relevant to the use of tumor markers was reviewed. Particular attention was given to reviews, including the few relevant systematic reviews, and to guidelines issued by expert panels. If possible, the consensus recommendations of the NACB Panels reported here were based on available evidence, i.e., were evidence based. An accompanying paper presents NACB recommendations relating to general quality requirements for tumor measurements and includes tabulation of important causes of false-positive tumor marker results that must also be taken into account (e.g., heterophilic antibody interference, high-dose “hooking,” etc.) (3).

Tumor Markers in Testicular Cancers26,27

BACKGROUND
About 95% of all malignant testicular tumors are of germ-cell origin; most of the rest are lymphomas, Leydig or Sertoli cell tumors, and mesotheliomas. Germ cell tumors of adolescents and adults are classified into 2 main types, seminomas and nonseminomatous germ cell cancers of the testis (NSGCT). Testicular cancers represent about 1% of all malignancies in males, but they are the most common tumors in men age 15–35 years. Testicular cancers are a significant cause of death in this age group in spite of the fact that presently more than 90% of the cases are cured (4). Germ cell tumors may also originate in extragonadal sites, e.g.,

the sacrococcygeal region, mediastinum, and pineal gland (5). Those of the sacrum are predominantly found in young males. Based on the histology, age of the patient at diagnosis, clinical behavior, and morphological characteristics, these tumors can be subdivided into 3 distinct entities with different clinical and biological characteristics (6–9): (a) teratomas and yolk sac tumors of newborns and infants, (b) seminomas and nonseminomas of adolescents and young adults, and (c) spermatocytic seminoma of the elderly. Seminomas and nonseminomas in adolescence and adulthood were the focus of attention when developing these recommendations.

The incidence of testicular cancers varies considerably in different countries. In the US about 7200 new cases are diagnosed each year (4), and the age-adjusted incidence is 5.2 per 100 000. The incidence is about 4-fold higher in white than in black men. In Europe, the age-adjusted incidence is lowest in Lithuania (0.9 per 100 000), intermediate in Finland (2.5 per 100 000) and highest in Denmark (9.2 per 100 000) (10). The incidence in various European countries has increased by 2%–5% per year. In the US the incidence increased by 52% from the mid-1970s to the mid-1990s (11). The cause of germ cell tumors is unknown, but familial clustering has been observed, and cryptorchidism and Klinefelters syndrome are predisposing factors (4).

At presentation most patients have diffuse testicular swelling, hardness, and pain. At an early stage a painless testicular mass is a pathognomonic finding, but testicular masses are most often caused by infectious epididymitis or orchitis. The diagnosis can usually be confirmed by ultrasonography. If testicular cancer is suspected, the serum concentrations of α-fetoprotein (AFP), human chorionic gonadotropin (hCG), and lactate dehydrogenase (LDH) should be determined before therapy. As a rule, orchectomy is performed before any further treatment, but may be delayed until after chemotherapy in individuals with life-threatening metastatic disease. After orchectomy, additional therapy depends on the type and stage of the disease.

Surveillance is increasingly used for seminoma patients with stage I disease, but radiation to the retroperitoneal and ipsilateral pelvic lymph nodes, which is standard treatment for stage Ia and Ib disease, is also used, as is short (single)-course carboplatin (12)]. About 4%–10% of patients relapse, and more than 90% of patients who relapse are cured by chemotherapy. About 15%–20% of stage I seminoma patients under surveillance have a relapse and must be treated with chemotherapy. Patients with stage I nonseminomatous tumors are treated by orchectomy. After this treatment, surveillance and nerve-sparing retroperitoneal lymph-node dissection are accepted treatment options. About 20% of patients under surveillance will have a relapse and require chemotherapy. Patients with stage II nonseminomatous tumors are treated with either chemotherapy or retroperitoneal lymph node dissection. Testicular cancer patients with advanced disease are treated with chemotherapy (4).

Serum tumor markers have an important role in the management of patients with testicular cancer, contributing to diagnosis, staging and risk assessment, evaluation of response to therapy, and early detection of relapse. Increasing marker concentrations alone are sufficient findings for treatment initiation. AFP, hCG, and LDH are established serum markers. In most cases of NSGCT, serum levels of one or more of these markers are increased, and in seminomas LDH and hCG are useful indicators. Other markers have been evaluated but provide limited additional clinical information.

To prepare these guidelines, we reviewed the literature relevant to the use of tumor markers for testicular cancer. Particular attention was given to reviews, prospective randomized trials that included the use of markers, and guidelines issued by expert panels. Only one relevant systematic review was identified. When possible, the consensus recommendations of the NACB panel were based on available evidence, i.e., were evidence based.

CURRENTLY AVAILABLE MARKERS FOR TESTICULAR CANCER

The most widely investigated tissue-based and serum-based tumor markers for testicular cancer are listed in Table 1. Also listed is the phase of development of each marker as well as the level of evidence (LOE) for its clinical use.

TUMOR MARKERS IN TESTICULAR CANCER: NACB RECOMMENDATIONS

A summary of recommendations from representative guidelines published on the use of tumor markers in testicular cancer is presented in Table 2. This table also summarizes the NACB guidelines for the use of markers in this malignancy. A number of groups have made detailed recommendations regarding the management of testicular cancer (13–21), with some of those relating to tumor marker use summarized in Table 3. Table 4 summarizes the prognostic significance of serum tumor markers in metastatic testicular cancer, according to the consensus statement of the International Germ Cell Consensus Group Classification, which remains the cornerstone for diagnosis and treatment of testicular germ cell tumors. Below, we briefly review the histological types of testicular cancer and present a more detailed discussion on the markers listed in these tables.
HISTOLOGICAL TYPES OF TESTICULAR CANCER

In the most recent WHO-Mostofi classification (8, 22), testicular cancers are subdivided into 2 major types, seminomas and NSGCT, which differ with respect to both marker expression and treatment. The incidence of seminoma peaks in the fourth decade of life and that of NSGCT in the third. Seminomas can be either pure seminomas or the rare spermatocytic seminomas that occur in older age groups. Most NSGCTs are a mixture of histological types, i.e., embryonal carcinomas, choriocarcinomas, teratomas, and yolk sac tumors. About 10%–20% of the nonseminomas also contain a seminoma component. These are classified as combined tumors according to the British classification (23), but as nonseminomas according to the WHO classification system (22). Teratomas are further subdivided as mature or immature. Somatic cancers of various types occasionally develop from a teratoma and are classified as nongerm cell malignancies. Metastases may contain any component occurring in the primary tumor, and occasionally components not detected in the primary tumor (22). Fewer than 10% of NSGCT contain a single tissue type, and all histological types of tissue should be described (24).

The precursor lesion of testicular seminomas and nonseminomas is carcinoma in situ (25), also re-
ferred to as intratubular germ cell neoplasia unclassified (ITGCNU) and testicular intratubular neoplasia. Carcinoma in situ cells are found within the spermato
goniaal niche of the seminiferous tubule in the adult testis in close proximity to the Sertoli cells, the nursing cells of spermatogenesis (26). The carcinoma in situ cells can be detected in the adjacent parenchyma of most invasive tumors and are more frequently associated with

NSGCTs than with seminomas (27). ITGCNU is considered to be the premalignant counterpart of an embryonic germ cell, most likely a primordial germ cell or gonocyte. This theory is supported by multiple findings, including epidemiology, morphology, immunohistochemistry, and molecular characterization (28, 29).

Recent data indicate that infertile men with bilateral microlithiasis have an increased risk (up to 20%) of developing testicular seminomas and NSGCTs.

A number of studies have linked the development of germ cell tumors to a deregulated G1/S checkpoint, possibly related to the lack of a functional retinoblastoma (RB1 gene) cell cycle regulator (45), and consequently no upregulation of p21 after induction of DNA damage. Cells without p21 show reduced cisplatin-induced DNA damage–repair capacity and increased sensitivity to cisplatin (46). The treatment-resistant mature teratomas show, in contrast to other invasive components, positive staining for multiple proteins potentially related to treatment resistance. In addition, they are positive for RB1 and p21, allowing them to go into G1/S cycle arrest (47, 48). These characteristics might explain the observation that residual mature teratoma is found in about 30%–40% of remnants of initial metastases after chemotherapy.

A predictive model for the histology of a residual retroperitoneal mass, based on primary tumor histology, prechemotherapy markers, mass size, and size reduction under chemotherapy, has been developed (49). Absence of teratoma elements or viable cancer cells in the primary tumor has been identified as the most powerful predictor for benign residual tissue (50). Caution is warranted, however, because small teratoma areas may be missed in the primary tumor, and absence of teratoma elements does not exclude occurrence of malignant cells in residual masses. These findings may again be related to the origin of these tumors (51), because RB1 expression is not found in human fetal gonocytes or ITGCNU (52, 53).

VASCULAR INVASION

Particular attention must be paid to the presence or absence of vascular invasion as a predictor of metastatic spread and occult metastases (54). Distinguishing venous from lymphatic invasion does not add information as to the risk of occult metastasis. Besides vascular invasion, high proliferative activity (assessed with the monoclonal antibody MIB-1), and to a lesser extent the presence of embryonal carcinoma in the primary tumor and a high pathologic stage, have been reported to be predictors of systemic spread in clinical stage I NSGCT [for review, see (55)]. However, the predictive value of this model is limited, because the group defined as high risk in fact has a 50% risk of occult metastasis, and the low risk group a 16% risk.

Prospective assessment of risk factors for relapse in clinical stage I NSGCT also showed that vascular invasion was the strongest predictive factor (56). With the addition of 2 other risk parameters (MIB-1 score >70% and embryonal carcinoma ≥50%), the positive predictive value increased to 63.6%. Thus, even with an optimal combination of prognostic factors and reference pathology, more than one-third of patients pre-
dicted to have pathologic stage II or a relapse during follow-up will not have metastatic disease and will be over-treated with adjuvant therapy. On the other hand, patients at low risk can be predicted with better accuracy (86.5%), suggesting that surveillance may be an option for highly compliant patients. Recently, cluster analysis has been used to identify prognostic subgroups in patients with embryonal carcinoma.

Serum Markers for Testicular Cancer

MARKER EXPRESSION AND TUMOR TYPE

Certain markers have been found to be informative for the classification of seminomas and NSGCT. Placental/germ cell alkaline phosphatase (PLAP) is detected in most seminomas and embryonal carcinomas and in 50% of yolk sac tumors and choriocarcinomas, but only rarely in teratomas. HCG is expressed by syncytiotrophoblasts, choriocarcinoma, and approximately 30% of seminomas. Of the other tissue markers, the stem cell factor receptor (c-KIT) has been used mainly to detect ITGCNU and seminoma, CD30 to detect embryonal carcinoma, and AFP to detect yolk sac tumors and a 10%–20% subset of embryonal carcinomas and teratomas. Recently, a potentially valuable marker, OCT3/4, also known as POU5F1, has been identified.

Although a large number of serum markers have been studied, only hCG, AFP, and LDH have thus far been shown to have independent diagnostic and prognostic value (Tables 1 and 2). The clinical value of other markers remains to be established. Table 5 summarizes analytical limitations of the assays available for some of the most important established and experimental tumor markers. The implications of these limitations for tumor marker use in routine clinical practice are discussed in greater detail below.

*AFP, α-fetoprotein; hCG, human chorionic gonadotropin; hCGβ, free β-subunit of human chorionic gonadotropin; hCGα, free α-subunit of human chorionic gonadotropin; LDH, lactate dehydrogenase; PLAP, placental (germ cell) alkaline phosphatase.

Clinical applications of serum tumor markers in testicular cancer

Diagnosis. Patients with a testicular germ cell tumor may present with a painless testicular mass, while others also have symptoms caused by metastatic disease. The clinical workup comprises physical examination, ultrasound of the testis, and computerized tomographic scan of the pelvis, abdomen, and chest. Determination of hCG, AFP, and LDH in serum before therapy is mandatory in all patients. The marker concentration in serum is dependent on histological type and tumor load, i.e., stage. In a recent large collaborative study 64% of the tumors were NSGCT, and 36% were seminomas. Of the latter, 77% of patients presented with stage I disease, i.e., tumor localized to the testis, and 21% had increased serum levels of hCG. Of those with NSGCT, 52% had stage I disease and 79% had increased marker levels [both hCG and AFP increased in 44%, only AFP in 26%, and only hCG in 9%...
In seminoma patients, hCG concentrations are usually below 300 U/L. Levels >1000 U/L are mostly associated with NSGCT. Levels >10000 U/L are mainly seen in patients with pure choriocarcinoma but occasionally may occur in seminoma. LDH is increased in 40%–60% of patients with seminoma or NSGCT (64). The classification of a tumor is based on histological examination, but if serum AFP is increased, a tumor classified as a seminoma is reclassified as NSGCT and treated accordingly (4).

**STAGING, RISK STRATIFICATION, AND SELECTION OF THERAPY**

Increased serum concentrations of AFP, hCG, and LDH are associated with adverse prognosis (65, 66). A high serum hCG concentration is a strong prognostic factor, and the risk of recurrence increases with increasing concentration (67). The International Germ Cell Cancer Collaborative Group has incorporated serum concentrations of hCG, AFP, and LDH in a scheme for classification of metastatic germ cell tumors (Table 4). Tumors are classified as having good, intermediate, or poor prognosis on the basis of marker levels, primary site of the tumor, and presence or absence of non-pulmonary visceral metastases (66).

The selection of treatment is based on tumor type and prognostic group. Stage I seminomas may be treated by orchiectomy alone, which leads to cure in 80%–85% of the cases. Orchiectomy in combination with radiotherapy of the abdominal lymph nodes leads to cure in 97%–99% of the cases, and this approach is routinely used in many centers. Without radiotherapy 15%–20% of the patients relapse, but most of these are cured by second line therapy. Therefore surveillance at increased frequency is an alternative to radiotherapy.

When treated by orchiectomy only, patients with stage I NSGCT have a 30% risk of relapse. The risk is higher (50%) if perivascular infiltration is present than if it is absent (risk 15%–20%). The relapse risk is very low if retroperitoneal lymph node dissection is performed in connection with primary therapy. This procedure is associated with morbidity and therefore surveillance is used as an alternative to retroperitoneal lymph node dissection. Chemotherapy is another alternative to retroperitoneal lymph node dissection but patients who undergo chemotherapy often have residual retroperitoneal tumors consisting of teratomas, which must be treated by surgery. If serum marker levels do not normalize or increase after retroperitoneal lymph node dissection, positive retroperitoneal lymph nodes or systemic disease requiring chemotherapy are most likely present (68, 69).

**FURTHER RISK STRATIFICATION**

Embryonal carcinoma is the most common cell type in NSGCT. Embryonal carcinoma is totipotential, and tumors with pure embryonal carcinoma are associated with early metastatic disease. Therefore, more accurate estimation of prognosis is needed for tumors containing this cell type. Cluster analysis of the serum markers AFP and hCG in combination with the tissue markers p53, Ki67, and apoptosis index suggest that a pattern with high Ki67, low apoptosis, and low p53 is associated with better survival than other patterns. Classification with this algorithm has been reported to be independent of the International Germ Cell Collaborative Group Classification (67). Confirmation of these results could provide a tool for more precise tailoring of therapy.

**MONITORING OF RESPONSE TO THERAPY**

If AFP or hCG in serum is increased before therapy, the rate of marker decline reflects the response to therapy. Persistent marker elevation after chemotherapy indicates residual disease and the need for further therapy (70, 71). Chemotherapy may induce a transient increase or surge in marker concentrations during the first week of treatment (72).

In the absence of residual disease after orchiectomy, the half-life of hCG is approximately 1.5 days and that of AFP 5 days (73, 74). During chemotherapy, half-lives >3.5 days for hCG or >7 days for AFP predict recurrence and adverse prognosis (75). Marker half-life is calculated from the slope of the logarithm of the marker concentration vs time. It is preferable to use marker concentrations from several time points and to calculate the half-life from the slope of the regression line (64). The half-life should be determined after the initial marker surge during 2 cycles of chemotherapy between days 7 and 56. A slow rate of marker decline is of potential use in poor-risk patients and may imply a need for more aggressive therapy (75).
The carbohydrate compositions of AFP derived from the liver and the yolk sac are different (87). Lectin binding can differentiate increased levels caused by tes-
tericular cancer and liver disease (88), but such methods are not routinely used. Patients who initially have increased AFP levels may have normal levels during a relapse if therapy has eliminated AFP-producing elements but not all other components (89). Moderately increased values that remain stable do not usually indicate relapse (86).

### NACB Testicular Cancer Panel Recommendation 5: Analytical Requirements for Measurement of AFP

AFP methods should be calibrated against WHO Standard 72/225 and the units in which results are reported (μg/L or kU/L) clearly stated. The detection limit for AFP assays should be ≤1 μg/L (i.e., ≤0.8 kU/L). Reference values should be established to reflect method bias. AFP may be raised due to benign diseases, maligancies other than testicular cancer, or nonspecific interferences, and these possibilities must be considered when interpreting results [LOE, not applicable; SOR, A].

### hCG and hCGβ

**Biochemistry and biology.** hCG is a member of the glycoprotein hormone family, which includes luteinizing hormone, follicle-stimulating hormone and thyroid stimulating hormone. All 4 contain a common α-subunit. The distinct β-subunits confer biological activity and display various degrees of homology, with that between the β-subunits of luteinizing hormone and hCG (hCGβ) being about 80%. hCGβ contains a 24–amino acid C-terminal extension not present in luteinizing hormone β, so antibodies to this part of the molecule are specific for hCG. Although the subunits lack hCG activity, hCGβ has been shown to enhance the growth of tumor cells in culture by preventing apoptosis (90). hCG is expressed at very high concentrations by the placenta and trophoblastic tumors, including choriocarcinoma of the testis. hCG is heavily glycosylated, hCGβ containing 6 and hCGα 2 carbohydrate chains. The glycosylation of hCG secreted by tumors is often different from that of hCG found in pregnant women. An antibody, B152, detects only a hyperglycosylated variant of hCG. This form predominates in early pregnancy and is possibly more cancer-specific than “normal” hCG (91).

**Nomenclature, assay methods, standardization, and reference values.** Specific determination of hCG is based on antibodies reacting with hCGβ (92). This practice has caused confusion in the nomenclature of hCG assays: the expressions “β-hCG” or “hCG-β assay” may denote assays measuring both hCG and hCGβ or only hCGβ. According to the nomenclature recommended by the IFCC, hCG denotes the intact αβ heterodimer, hCGβ the free β-subunit, and hCGα the free α-subunit (93). Assays should be defined according to what they measure, i.e., hCG and hCGβ separately or hCG and hCGβ together (64, 94).

Assays for hCG are currently calibrated against the Fourth International Standard (IS 75/589), in which concentrations are expressed in International Units (IU) based on bioactivity. It is difficult, however, to compare concentrations of hCG with those of hCGβ and hCGα, which are expressed in different arbitrary units of the relevant International Standards (IS 75/551 and IRP 75/569, respectively). Recently established WHO Reference Reagents have values assigned in molar concentrations, which should facilitate direct comparison of hCG and hCGβ concentrations in the future (93, 95).

Because seminomas may produce solely hCGβ and not intact hCG, it is essential that both hCG and hCGβ are measured when monitoring testicular cancer (14, 96) Recommendations about antibody combinations that recognize most important forms of hCG-related isofoms and are appropriate for use in oncology have been published (94). Assays recognizing both hCG and hCGβ often use antibodies to epitopes on the C-terminal peptides of hCGβ, but the relatively low affinities of these antibodies may limit assay sensitivity (94). Theoretically it should be possible to improve detection of testicular cancer by using separate assays for hCG and hCGβ (64, 96) but this remains to be confirmed.

hCG is secreted at low levels by the pituitary, producing plasma levels that are measurable by sensitive methods. The serum concentrations may increase with patient age, particularly in women after menopause (97, 98). For most assays, the upper reference limit of hCG is stated to be 5–10 U/L. When determined by ultrasensitive methods, the upper limit in postmenopausal women is 5 U/L and in menstruating women is 3 U/L. The upper reference limit for men younger than 50 years is 0.7 U/L and for men older is 2.1 U/L (98). Cutoff values lower than the commonly used 5–10 U/L can be used to diagnose patients with testicular cancer. However, although most men with testicular cancer are young, their hCG levels may be increased due to testicular malfunction. Therefore diagnosis of active disease in a patient with a history of a germ cell tumor requires sequential determinations and rising values. The detection limit of most commercial assays does not allow reliable measurement of levels below 5 U/L and the utility of ultrasensitive assays and lower cutoff values needs to be determined (64). When expressed in molar concentrations, 5 U/L of hCG corresponds to 15 pmol/L. The upper reference limit for hCGβ is 2 pmol/L and is independent of age and sex (98).
Specificity and confounding factors. It is important to note that chemotherapy often causes gonadal suppression that increases the hCG levels. Such hypogonadism can also be spontaneous. This can be confirmed by measurement of serum luteinizing hormone and follicle-stimulating hormone and, when necessary, suppression with testosterone replacement (99). Therefore, hCG levels increasing from below 2 up to 5–8 U/L during chemotherapy are often iatrogenic and do not necessarily indicate relapse. Moderately increased levels of hCG may be of pituitary origin, especially if accompanying serum levels of luteinizing hormone and follicle-stimulating hormone exceed 30–50 U/L, and are attributed to interrupted feedback inhibition from the gonads. This can be confirmed by short-term testosterone treatment, which suppresses pituitary secretion of hCG (100, 101).

Nontrophoblastic tumors may in extremely rare cases produce hCG, whereas hCGβ is often expressed at moderate levels by a large variety of tumors, including ovarian, gastrointestinal, bladder, lung, and head and neck cancers (101). Some patients with such tumors will have increased hCG levels when measurement is carried out by an assay recognizing both hCG and hCGβ.

Falsely increased results for serum hCG can be caused by heterophilic antibodies. This phenomenon has been reported only in women (102) but there is no reason why it should not also occur in men. False-positive results can be identified by analysis of hCG in urine or by repeating the assay after adding a blocking agent (e.g., nonimmune mouse IgG) to the sample to block the interference (64, 102).

Apparently false-negative results will be obtained with assays measuring only hCG if the tumor produces hCGβ but not hCG. Although this situation is more common in seminoma patients (103), it may also occur in NSGCT patients (104).

**NACB TESTICULAR CANCER PANEL RECOMMENDATION 6:**
ANALYTICAL REQUIREMENTS FOR MEASUREMENT OF HCG
It is essential that both hCG and hCGβ be measured when using hCG to monitor testicular cancer patients, either using a method recognizing a broad spectrum of hCG-related isoforms or separate specific assays. hCG and hCGβ should be recognized on an equimolar basis with a detection limit of ≤1 U/L. IFCC hCG nomenclature should be used to describe the method used. The possibility of interferences (e.g., from heterophilic antibodies) and transient increases (e.g., due to chemotherapy) must be considered when interpreting hCG results [LOE, not applicable; SOR, A].

**NACB TESTICULAR CANCER PANEL RECOMMENDATION 7:**
ANALYTICAL REQUIREMENTS FOR MEASUREMENT OF LDH
Because LDH is measured enzymatically and the values are method-dependent, the degree of elevation is therefore most conveniently expressed relative to the upper reference limit. LDH-1 can be determined by zymography or by immunoprecipitation of the other isoenzymes and determination of residual catalytic activity. LDH is expressed in many tissues and increased levels may be caused by a wide variety of diseases. Despite its lack of specificity, LDH is a useful marker, especially for staging of seminoma and NSGCT (108). Hemolysis may cause falsely increased values and should be avoided.

**PLACENTAL ALKALINE PHOSPHATASE**

Biochemistry and biology. A tumor-associated isoenzyme of alkaline phosphatase was first described in a patient with lung cancer and later detected in serum of patients with other cancers and identified as placental alkaline phosphatase (PLAP) (110). In fact, 2 genes encode the proteins detected as PLAP activity, i.e., the placental (PLAP) and germ cell enzymes. Both genes map to chromosome 2 and the proteins cannot be distinguished from each other using routine enzymatic or
immunohistochemical methods (111). PLAP is increased most frequently in patients with seminoma (60%–70%, 112, 113) and less frequently in those with other germ cell tumors, including ITGCNU (24). An enzymatic method can be used to detect ITGCNU cells in frozen tissue sections (114).

Assay methods, standardization, and reference values. PLAP has usually been determined by zymography but it can be also be measured by immunoassay or enzymatically after immunocapture (113). The result should be compared with locally determined reference values. Because of homology with other alkaline phosphatase isoenzymes, antibody selection is critical. However, the antibodies available so far cannot distinguish between the PLAP and germ cell alkaline phosphatase isoenzymes. Therefore, PLAP denotes both of these isoenzymes.

Specificity and confounding factors. Serum concentrations of PLAP are increased up to 10-fold in smokers and its measurement is therefore of little value in this group (113). This fact and the paucity of commercial assays limit its clinical application, and serum assays for PLAP are not routinely included in the diagnostic workup of testicular cancer patients.

OTHER MARKERS

Although pregnancy-specific B1 glycoprotein and hCG are both expressed in trophoblastic cells, hCG is the superior marker (115). Consequently, pregnancy-specific B1 glycoprotein is not routinely measured. Neuron-specific enolase is increased in about 30%–50% of patients with seminomas and less often in NSGCT patients (16, 116, 117), but in spite of these promising results the use of neuron-specific enolase is limited.

KEY POINTS: TUMOR MARKERS IN TESTICULAR CANCER

Tumor markers are of central importance in the diagnosis, staging, risk assessment, and monitoring of patients with testicular cancer. Several serum markers have been described but only AFP, hCG, and LDH have been thoroughly validated and shown to have independent prognostic value. Several tissue markers may prove to be clinically important in the diagnosis and classification of testicular germ cell tumors. Germ cell tumors also display typical chromosomal abnormalities and amplification of 12p is sufficiently characteristic to be useful in the clinic to identify extratesticular germ cell tumors. Developments in DNA-based diagnostics have revealed a number of changes that may in the future enable more accurate stratification of prognosis.

Tumor Markers in Prostate Cancer29,30

BACKGROUND

Prostate cancer is the most common tumor in men in the US. In 2007, 218,890 new cases and 27,050 deaths

were predicted. Although prostate cancer is unequivocally lethal in some patients, most men die with rather than of their cancer (118). Autopsy data suggest that 42% of men older than 50 years old have cancerous foci in their prostates but prostate cancer will be diagnosed in only approximately 16% of men during their lifetime and only a quarter of these will die from it. Many more men die with than of prostate cancer (119). Current incidence rates of clinical disease are 15-fold higher in the US than in Japan despite similar frequencies of histological cancer. Hence, the far greater prevalence of histological than symptomatic cancer has been cited to support a conservative, noninterventionist approach to this disease. However, once prostate cancer reaches advanced stages either locally or systemically with bone metastases, or becomes refractory to hormone therapy, little if any therapeutic means for cure are available.

The optimal management of patients with prostate cancer requires the use of the tumor marker prostate-specific antigen (PSA) in all instances and disease states. The use of PSA-related isoforms is appropriate in certain specific circumstances. Here we present new National Academy of Clinical Biochemistry guidelines on the use these and other serum-based tumor markers in prostate cancer. A summary of relevant guidelines published by other expert panels on this topic is also provided.

To prepare these guidelines, the literature relevant to the use of tumor markers in prostate cancer was reviewed. Particular attention was given to reviews (including systematic reviews), prospective randomized trials that included the use of markers, and guidelines issued by expert panels. Where possible, the consensus recommendations of the NACB Panel were based on available evidence, i.e., were evidence based.

CURRENTLY AVAILABLE MARKERS FOR PROSTATE CANCER
Commercially available PSA markers cleared by the FDA for use in the management of patients with prostate cancer are listed in Table 6, together with the phase of development for each marker as well as the LOE for their clinical use (120).

TUMOR MARKERS IN PROSTATE CANCER: NACB RECOMMENDATIONS
Table 7 summarizes the NACB guidelines for the use of PSA markers in prostate cancer together with recommendations from other representative guidelines published on the use of tumor markers in prostate cancer, including recently published recommendations issued by the United Kingdom National Institute for Health and Clinical Excellence (NICE), which has undertaken a systematic review of best available evidence (121). Although other markers have been investigated (Table 8), based on currently available evidence only the use of PSA and its isoforms can be recommended in prostate cancer. Below we present a more detailed discussion of the use of these measurements.

PSA Markers in Patient Management

PSA MARKERS IN THE SCREENING AND EARLY DETECTION OF PROSTATE CANCER
The widespread measurement of serum PSA is largely responsible for the increased incidence of prostate cancer in the US during the past 2 decades. As demonstrated by epidemiological data showing both a marked increase in the number of men diagnosed with prostate cancer and a profound migration toward earlier stage disease at the time of diagnosis (122), there is strong evidence supporting the growing concern that such “stage migration” causes overdiagnosis and overtreatment of men with indolent cancer, a condition that may pose little threat to the life or health of the patient (123). The usefulness of PSA screening has also been questioned owing to poor specificity when serum concentrations are modestly increased (124). Although extensive evidence shows that elevations of PSA in serum are exclusively associated with disease conditions in the prostate, such findings are not cancer specific, occurring also in other conditions such as benign prostatic hyperplasia and prostatitis. This well-documented lack of specificity of the conventional PSA test even prompted researchers to question whether any association exists between serum PSA levels and prostate cancer (125). In contrast, reports from many other investigators have shown that there is very strong evidence of a very significant association between serum PSA levels and presence or outcome of prostate cancer (126–130). Also, the lack in specificity of the PSA test is less critical in monitoring patients with a prostate cancer diagnosis, for whom PSA is the most important marker in evaluating response to therapeutic interventions and in detecting tumor relapse. Although potentially valuable as part of multivariate panels to identify aggressive cancers and/or cancer recurrence, measurement of prostatic acid phosphatase alone does not provide any clinically useful information additional to PSA measurement (131, 132), and therefore is not recommended by the NACB.

NACB PROSTATE CANCER PANEL RECOMMENDATION 1:
CHOICE OF TUMOR MARKER FOR MANAGEMENT OF PATIENTS WITH PROSTATE CANCER
PSA is currently the most useful serum tumor marker in management of prostate cancer patients and is required in all stages of the disease [LOE, III; SOB, A].

*Continued on page e27*
Population-based median levels are <0.6 μg/L for men ≤50 years, the vast majority of whom have yet to develop any signs or symptoms of prostate cancer or benign enlargement of the gland (130, 133, 134). The 80th centile is close to 1 μg/L, and the 90th centile is about 1.25 μg/L (130). An upper limit of normal according to the 95th percentile for men ≤50 years has never been implemented in clinical practice, but would correspond to a PSA level of about 1.5 μg/L. A modest increase in PSA levels in older men reflects a higher frequency of benign prostate conditions at higher age. Population-based demographics of PSA levels for men 50 –70 years old show that 8%–9% of these men have PSA levels ≥4.0 μg/L, while 11%–12% have PSA levels ≥3.0 μg/L, and as many as 20% of all men have serum PSA levels ≥2.0 μg/L (135).

In men who present with modestly increased levels of PSA in serum (i.e., 4–10 μg/L), there is extensive evidence showing that histopathologic examination of tissue harvested by systematic prostate biopsies confirms presence of prostate cancer in 25%–35% of these men (136, 137). When serum PSA levels rise above 10 μg/L, the cancer specificity of the test is 40%–50% or higher. Current recommendations in the US suggest that most men older than 50 years should have annual prostate cancer screening with PSA and digital rectal examination (DRE), and that men should be advised to have biopsies when the DRE is abnormal or when the PSA level in serum is ≥4.0 μg/L (138).

The NICE guidelines conclude that the serum PSA level alone is a poor predictor of the presence of prostate cancer and should not automatically lead to a prostate biopsy, particularly because many cancers diagnosed on this basis alone will be of low risk, causing little or no impact on life expectancy (121, 139).

These recommendations all have some limitations, as has recently been discussed (140). The PSA cutoff of ≥4.0 μg/L represents a clinical decision limit that was introduced on the basis of a single report evalu-

* Based on Table 3 of the Prostate Cancer Foundation Report to the Nation on Prostate Cancer (563).

b BPH, benign prostatic hyperplasia; LOE as defined in Table 6; PSMA, prostate-specific membrane antigen; RT, reverse transcription; ASR, analyte-specific reagent.
uating the optimal combination of sensitivity and specificity of the PSA test in a study cohort, and the distribution of values observed in this original study may no longer apply (141). It is debatable whether a PSA cut-point lower than 4 μg/L should be recommended. Also debatable is whether decisions to recommend prostate biopsy should be based solely on a single PSA cut-point value (e.g., ≥4 μg/L). Lower PSA cutoffs increase the cancer detection rate at the expense of increasing the number of men advised to undergo biopsy. It has also been clearly demonstrated, however, that 20% or more of all men who have PSA levels from 2.0 (or 3.0) up to 4.0 μg/L are found to have prostate cancer at biopsy (142, 143). This finding was confirmed in a recent study, in which prostate cancer was diagnosed by biopsy in as many as 15.2% of all 2950 biopsied men with PSA values <4.0 μg/L (128). This study showed that the prevalence of prostate cancer in men 62–91 years old increased from 6.6% in men with PSA of 0–0.5 μg/L, 10% with PSA 0.6–1.0 μg/L, 17% with PSA 1–2 μg/L, up to 23.9% with PSA 2.1–3.0 μg/L, and 26.9% with PSA 3.1–4.0 μg/L (128). Also, the prevalence of high-grade prostate cancer increased with increasing PSA values. Hence, the positive predictive value of the PSA test in terms of biopsy-proven (histological) prostate cancer is similar for men with a PSA value between 2–4 μg/L and those with a PSA value between 4–10 μg/L (136, 144).

The across-the-board recommendation of annual PSA testing for men older than 50 years (138) is overly simplistic and fails to alter testing frequency based on the individualized risk imparted by previously determined PSA levels. For example, a 55-year-old man with a baseline PSA of 0.4 μg/L is much less likely to develop prostate cancer in the future than a similarly aged man with a baseline PSA of 3.3 μg/L. Stenman et al. (126) used frozen serum samples and information from a health examination survey in Finland, and Gann et al. (145) used information from the Physicians’ Health Study to examine the usefulness of PSA for identifying men in whom prostate cancer subsequently was or was not clinically diagnosed. The data of Gann et al. suggest that men with PSA levels between 2.0 and 3.0 μg/L have 5.5-fold higher relative risk for diagnosis of prostate cancer than men with PSA levels <1.0 μg/L. In the former group, serum PSA levels reached 2–3 μg/L on average more than 5 years before the cancer was detected by DRE. Recently, Lilja et al. (130) demonstrated a very strong association between PSA levels in blood collected more than 20 years before prostate cancer diagnosis and the likelihood of that diagnosis in a large representative population of Swedish men age 44–50 years who had not previously undergone PSA testing. These data and those reported from others (129) suggest that risk stratification during early middle age may be important to consider in refining current imperfect early cancer detection strategies. Several additional issues particularly relevant to screening programs are discussed below.

AGE-SPECIFIC REFERENCE INTERVALS FOR PSA

Because serum PSA levels gradually increase with age in men older than 40 years, age-specific reference intervals have been proposed with the expectation that their implementation would increase cancer detection rates in younger men by lowering the cut-point and would increase specificity in older men by raising the cut-point (146). Although there is no consensus, many experts—including a majority of opinion of the National Comprehensive Cancer Network—favor the use of clinical decision limits lower than 4.0 μg/L for serum PSA in younger men. The NACB, however, is not yet convinced of the net benefit of this protocol in the absence of additional test(s) that could significantly increase diagnostic specificity (i.e., reduce unnecessary biopsies). At the same time the NACB advises caution in increasing the decision limit above 4.0 μg/L, because this could result in failure to diagnose clinically significant tumors in men who might potentially benefit from early treatment (147). Hence, contrary to previously issued recommendations (148), the NACB does not endorse the use of age-specific reference ranges.

NACB PROSTATE CANCER PANEL RECOMMENDATION 2: CLINICAL DECISION LIMITS

Given the controversy regarding the use of PSA to detect very small tumors, reported benefits arising from lowering the clinical decision limit for biopsy below 4 μg/L are too uncertain to mandate any general recommendation. Cut-points lower than the commonly used 4 μg/L limit will increase sensitivity with a concomitant decrease in specificity unless other adjunctive tests or measures are employed to increase specificity. Conversely, use of clinical decision limits for PSA higher than 4.0 μg/L decreases the sensitivity, which results in the missed diagnoses of clinically significant tumors in men who might potentially benefit from early treatment [LOE, not applicable; SOR, B].

NACB PROSTATE CANCER PANEL RECOMMENDATION 3: AGE-SPECIFIC REFERENCE INTERVALS FOR PSA

Age-specific reference intervals should not be used for PSA [LOE, expert opinion; SOR, B].
INCREASING PSA SPECIFICITY IN SCREENING FOR PROSTATE CANCER

The total PSA in circulation roughly corresponds to the sum of circulating free PSA (fPSA) and PSA bound as a stable complex to α-1-antichymotrypsin. The free fraction constitutes from 5% up to more than 40% of the total (149). Free and bound forms may be selectively detected by commercially available assays without any significant interfering cross-reaction (150). Several composite measures have been proposed to improve the specificity of a single serum total PSA concentration for the early detection of prostate cancer. PSA density (151–153), PSA velocity (154), PSA doubling time (155, 156), and percentage of free PSA (%fPSA) (157–161) have all been evaluated in this context, but only %fPSA has been widely validated and implemented in clinical practice. Men with benign disease generally present with higher %fPSA than men with prostate cancer (and no benign enlargement). Unfortunately, concurrent benign prostatic enlargement and prostate cancer complicates interpretation of %fPSA data (162). Nevertheless, in a systematic review carried out in 2005, the use of %fPSA was suggested as a means of decreasing the number of unnecessary biopsies, particularly for men with PSA levels of 4–10 µg/L (163). In accord with the conclusions of a recent meta-analysis (164), the current NACB Panel and the European Group on Tumor Markers (EGTM) (148) both recommend the use of %fPSA as an aid in distinguishing men with prostate cancer from men with benign disease in selected high-risk groups, e.g., when total PSA is <10 µg/L and DRE is negative. In particular, %fPSA may be useful in identifying men who have prostate cancer despite initial negative biopsy findings. In men with low %fPSA suspected to indicate a high risk of harboring malignant disease, a cancer diagnosis may become evident after a repeat biopsy. This recommendation is tempered by the need to validate the medical decision limit for each fPSA and total PSA commercial assay combination (165).

More than 95% of the immunodetectable complexed PSA (cPSA) fraction is bound to α-1-antichymotrypsin with <5% bound to other complex ligands, e.g., α-1-protease inhibitor (157, 166–168). PSA bound to α-2-macroglobulin is not detected by current immunoassays for PSA. Levels of cPSA in blood can be determined either directly using assays for PSA bound as a stable complex to α-1-antichymotrypsin (157, 158, 169), which first block access to fPSA and then measure levels of cPSA (170), or indirectly by subtracting fPSA from total PSA levels (171) using 2 assays designed to work together and standardized appropriately. Measurement of cPSA alone provides comparable cancer detection to total PSA but appears to give somewhat better specificity in a narrow concentration range (172). However, cPSA levels alone cannot achieve specificity similar to that of %fPSA (170).

GUIDELINES FOR THE EARLY DETECTION OF PROSTATE CANCER

The American Cancer Society has issued guidelines related to the early detection of prostate cancer. These guidelines recommend an annual screening with DRE and serum PSA measurement beginning at the age of 50 in men at average risk with at least 10 years of life expectancy (138). Although PSA is considered the best biochemical test currently available to detect prostate cancer, a DRE should also be included whenever possible, according to the American Cancer Society. Screening at earlier age (45 years or even 40 years) is warranted in men at increased risk, including those of African-American descent and those with one or more first-degree relatives with prostate cancer. Both of these groups often develop prostate cancer several years earlier than the general population and also tend to present with a more aggressive type of cancer (173).

The recommended follow-up testing of high-risk individuals initially screened at 40 years of age depends on the PSA result. Those with PSA levels <1 µg/L would resume testing at 45 years of age, those with levels >1 but <2.5 µg/L would be tested annually, and those with levels ≥2.5 µg/L would be evaluated further and considered for biopsy (138).

These guidelines do not endorse a general recommendation for mass screening, but support the notion that individual men should be informed of the benefits and limitations of prostate cancer screening before making their decision, as for example is recommended in the United Kingdom through the Prostate Cancer Risk Management Program (174) and by NICE (121, 139, 174). Much greater emphasis than previously is being placed on informed decision-making by the individual. This topic has recently been the subject of a systematic review in which PSA decision aids and evaluations were identified and appraised (175). The authors concluded that PSA decision aids improve

NACB PROSTATE CANCER PANEL RECOMMENDATION 4: USE OF %fPSA IN DIAGNOSIS

The use of %fPSA is recommended as an aid in distinguishing men with prostate cancer from men with benign prostatic hypertrophy when the total PSA level in serum is within the range of 4–10 µg/L and DRE is negative, most frequently in men undergoing repeat biopsy, in selected high-risk groups and particularly in identifying men who have prostate cancer despite initial negative biopsy findings. The clinical decision limit must be properly validated for each combination of free and total PSA assays [LOE, I; SOR, A].
knowledge about PSA testing, at least in the short term. There are many issues to consider, including the disparity between incidence and mortality associated with prostate cancer, because many more men are diagnosed with prostate cancer than eventually die from it. However, early detection affords the opportunity to detect organ-confined disease when curative treatment is possible. Metastatic disease now constitutes only about 5% of initial diagnoses in the US, a dramatic fall from the 50% incidence rate of the pre-PSA era (122). Nevertheless there are still many uncertainties concerning treatment of early stage disease, including the preferred treatment for clinically localized prostate cancer.

**MERITS OF EARLY DETECTION OF PROSTATE CANCER**

Because of the uncertainties regarding prostate cancer treatment, considerable debate is ongoing regarding the merits of early detection of prostate cancer, and not all physician organizations advocate routine screening (176). Although the American Urological Association endorses the American Cancer Society policy statement on the early detection of prostate cancer, recommendations of other organizations differ regarding the benefit of prostate cancer screening (177, 178). Arguments against screening are based on the fact that there is no conclusive evidence from any randomized trials that early detection and treatment influence overall mortality, whereas the standard treatments for organ-confined prostate cancer are associated with a significant frequency of side effects. Currently, the US Preventive Task Force, the American Academy of Family Physicians, the American College of Physicians, the National Cancer Institute, and the EGTM do not recommend population-based prostate cancer screening (177, 178). The overriding concern is that current screening modalities result in overdiagnosis and overtreatment of early stage disease that may not be clinically significant, as has recently been reviewed (179).

The NACB and the EGTM recommend that widespread implementation of screening for prostate cancer in the general population should await the final outcome of ongoing prospective randomized studies, in particular the European Randomized Screening for Prostate Cancer (ERSPC) trial (180), which are sufficiently powered to establish whether early detection and treatment decreases prostate cancer mortality. The ERSPC trial has been underway for 10 years, with results expected in 2010 (181). Long-term multicenter trials to determine the impact of prostate cancer screening on survival are also ongoing in the US under the aegis of the National Cancer Institute and the US Public Health Service (182).

With no clear-cut evidence as yet that prostate cancer screening is of net benefit, proponents of screening have pointed to the association of PSA testing with earlier cancer stage at detection and reduced mortality arising from prostate cancer. Registry data from heavily and sparsely screened male populations in Austria provide a case in point. The expected death rate from prostate cancer (183) declined much more in the Tyrol, a heavily screened section of the country, than in less intensely screened areas (184). The decrease in observed mortality was associated with a shift toward a more favorable stage at diagnosis, in particular an increase in the proportion of organ-confined disease. The inference is that early detection and availability of effective treatment resulted in a corresponding improvement in disease-specific survival. A similar trend has been observed in data from the National Cancer Institute’s Surveillance, Epidemiology and End Results (SEER) program, from a study conducted in Olmsted County, Minnesota (185), and from a comparison of prostate cancer mortality in the US and the United Kingdom between 1975 and 2004 (186).

Although recent data suggest that the apparent stage shift to early stage disease and subsequent treatment of localized prostate cancer detected with PSA have positively influenced mortality rates, it is still an open question whether early detection and therapeutic intervention alters the natural history of the disease, as observed benefits may be the result of selection or lead-time bias (187). The stage at diagnosis may be more dependent on the biological behavior of the tumor (aggressiveness) than on delay in presentation, and early detection may not have a significant impact on mortality. An increase in the proportion of localized prostate cancers that are being treated may account for some of the change in the mortality statistics (181).

Currently there is insufficient evidence either to support or refute the routine use of mass, selective or opportunistic PSA-based screening, and it is equally unclear whether to advise against the use of PSA-based screening, for which success in reducing prostate cancer mortality has yet to be demonstrated. Currently, no robust evidence from randomized controlled trials is available regarding the impact of screening on quality of life, the disadvantages of screening, or its economic value. Results from 2 ongoing large-scale multicenter randomized controlled trials that will be available in the next several years are required for evidence-based decision-making regarding prostate cancer screening (188).
screening studies (e.g., the European Randomized Screening for Prostate Cancer trial in Europe) which are due to be completed by 2010 [LOE, III; SOR, A].

PSA IN PATIENT MANAGEMENT

The optimal treatment of early stage prostate cancer has yet to be established. Treatment options include expectant management (active surveillance or watchful waiting), radical prostatectomy, or radiation therapy (external beam radiation or brachytherapy) (139). Alternative treatment modalities (e.g., cryosurgery or high-intensity focused ultrasound) await evaluation of their long-term results. Patients with advanced (metastatic) disease are typically offered hormonal therapy to deprive the prostate of androgen stimulation. PSA synthesis by differentiated prostate cells is greatly impaired by such treatment and the PSA levels in blood reflect tumor burden differently from before androgen deprivation. When the disease becomes refractory to either first- or second-line androgen deprivation, patients may be entered into chemotherapy or experimental protocols with various agents (e.g., Taxotere). The assessment of PSA levels in the blood plays a cardinal role in all aspects of the management of prostate cancer from surveillance to selection of optimal treatment to estimation of prognosis to posttherapeutic monitoring. fPSA measurement has not been shown to offer any advantages over total PSA during the follow-up of prostate cancer (189).

The treatment selected after detection of prostate cancer depends critically on whether the disease is confined to the prostate. Radical prostatectomy is primarily an option for patients with organ-confined disease, although patients with extracapsular disease may also benefit from radical surgery (190). However, the extent of disease is difficult to predict accurately. PSA alone is not informative (191), but in combination with the clinical stage and Gleason score predicts reasonably well the pathological stage of localized prostate cancer. Predictive tables that incorporate these parameters have been published (192–194) and are used by physicians to estimate the probability of organ-confined disease and to determine whether radical prostatectomy is indicated. It is recommended by NICE that urological multidisciplinary teams should assign a risk category to all men with newly diagnosed localized prostate cancer, taking these parameters into account (121, 139).

Assessment of changes of PSA levels with time (PSA velocity or PSA doubling time) was first introduced in 1992 (154), with a rapid increase indicating a higher risk for subsequent development of prostate cancer. Results of several studies further suggested that a more rapid rise in PSA before treatment is correlated with aggressive disease and early recurrence after treatment. In more recent studies reported by D’Amico et al. (195, 196) a PSA velocity of more than 2.0 μg/L/year measured during the year before diagnosis was shown to be significantly associated with prostate cancer-specific mortality. Recently, Carter et al. reported evidence that total PSA velocity could also be used to predict life-threatening prostate cancer up to 15 years before diagnosis (197). However, to demonstrate that PSA velocity has important clinical value, it must also be unequivocally shown that a multivariable model that incorporates both PSA and PSA velocity (e.g., addition of PSA velocity to a model that includes total PSA, age, and date of diagnosis) is superior to the model that uses PSA alone. This LOE appears still to be lacking, even in the most recently reported studies on this subject.

Following successful surgery, PSA should decrease to undetectable levels (198, 199). Persistently increased PSA provides evidence of residual disease. However, the converse does not always hold, namely that undetectable PSA postoperatively indicates a surgical cure. Considerable time may elapse before residual disease becomes evident through detectable PSA. Most commonly, residual disease will become evident within 3 years of surgery. Up to 20%–30% of the men who undergo radical prostatectomy present with residual disease during the first 10 years after surgery.

A rising PSA level after radical prostatectomy is a biochemical sign of recurrent disease that typically predates other signs of progression by many years. However, not all patients with biochemical recurrence will progress to symptoms of clinical disease and metastatic spread in their lifetimes and require treatment (200, 201). Factors reported to predict the time course to the development of metastatic disease include time to biochemical recurrence, tumor grade (Gleason score), and PSA doubling time (156, 161). These parameters can be used to estimate the likelihood of patients remaining free of overt metastatic disease and allow physicians to stratify patients into low-risk and high-risk categories and to make better treatment decisions.

Monitoring response after initial treatment and evaluating outcome during subsequent therapy are significant clinical applications of PSA determinations. Measurement of PSA provides essential information about the efficacy of surgery or radiation therapy, helps establish the possibility of residual disease (local or distant), signals recurrent metastatic disease before it can be detected by other conventional diagnostic procedures, and provides a useful adjunct in the evaluation of therapeutic response.
PSA may provide the earliest measure of treatment efficacy or disease recurrence, and as such influence the patient’s perception of well-being. For some patients, it may be most appropriate to stop measuring PSA, particularly if effective alternative treatments to counter adverse findings are not available (148).

**PSA MARKERS IN THE POSTTREATMENT MONITORING OF PROSTATE CANCER**

Following treatment, it is the Panel’s view that a single PSA measurement at or near the lower detection limit of the assay is not sufficient to diagnose recurrence of prostate cancer. Rising PSA levels demonstrated by repeat or serial measurements provide much more reliable evidence (121, 139, 202). Following radical prostatectomy, circulating PSA declines to undetectable levels if the prostate cancer was organ-confined and all residual prostate tissue surgically excised. Sustained detection of PSA suggests either incomplete resection or metastatic deposits. If ultrasensitive PSA assays are used in this setting, the functional detection limit of the assay should be established and should correspond to the lower reporting limit.

At present, evidence is equivocal regarding the clinical benefit of reporting biochemical recurrence of prostate cancer at PSA levels below 0.4 µg/L (200). Recently, however, salvage radiation therapy following prostatectomy, circulating PSA declines to undetectable levels when PSA levels are still very low (≤0.5 µg/L) (203). The recurrence limit is less clear following radiation therapy because of the typically slower decline in circulating PSA concentration. The American Society for Therapeutic Radiation and Oncology has defined biochemical recurrence as a rise of 2 µg/L or more above the nadir PSA, after external beam radiotherapy with or without hormonal therapy (204).

Monitoring with PSA after treatment for prostate cancer is a mainstay of clinical practice, although the clinical utility of PSA is variable and depends on the disease stage of the individual patient. As has recently been observed, the lack of high quality information and paucity of clinical trials hampers development of guideline recommendations for prostate cancer, but implementation of available guidelines are likely to improve prostate cancer outcomes while reducing unnecessary, ineffective, and costly care (140). PSA has high sensitivity for detecting recurrence after radical prostatectomy but is less sensitive in detecting recurrence following radiation therapy. For monitoring hormonal treatment, PSA provides a sensitive tool with which to verify treatment response and detect tumor growth (recurrence). However, in patients with advanced disease who suffer recurrence during androgen deprivational therapy, PSA has only limited usefulness for predicting survival outcome.

---

**NACB PROSTATE CANCER PANEL RECOMMENDATION 6: USE OF PSA IN THE POSTTREATMENT MONITORING OF PROSTATE CANCER**

PSA is recommended for management of patients with prostate cancer to monitor disease status following treatment [LOE, III; SOR, A].

**USE OF NOMOGRAMS INCORPORATING PSA TO MANAGE PROSTATE CANCER**

Nomograms incorporating one or more factors provide the most accurate means of individualizing therapy and predicting outcome, and reflect the most recent advances in patient management (205). Rather than relying on physician experience or general risk assessments of patient populations with similar characteristics, the nomograms assess treatment options or prognosis based on computerized models of Cox proportional hazards regression analysis. Predictive outcomes provided by computer models are not perfect, but nomograms can be extremely useful in assisting with treatment decisions. On occasion, it may be difficult to select the best nomogram when several competing versions apply to the same clinical decision. Kattan and coworkers (205, 206) have developed pre- and postoperative nomograms, incorporating PSA together with Gleason score and other variables, to predict disease recurrence following radical prostatectomy.

**PREANALYTICAL, ANALYTICAL, AND POSTANALYTICAL CONSIDERATIONS**

A number of factors in the preanalytical, analytical and postanalytical stages can affect the clinical interpretation of PSA results and must be carefully considered. A number of these factors were the subject of a systematic review carried out in 2001 (207).

**PREANALYTICAL SPECIMEN PROCESSING AND STORAGE**

It is desirable to collect blood before any manipulation of the prostate by DRE, cystoscopy, or prostate biopsy (166). If prior collection is not possible, then it is prudent to delay several days after DRE before drawing blood for PSA, although in most men DRE does not cause a clinically relevant change in circulating PSA concentration (166). Following prostate biopsy or surgery, the recommended delay is several weeks to permit sufficient time for the PSA bound as a stable complex to α-1-antichymotrypsin to be eliminated from the blood circulation, although the kidneys rapidly clear from the blood any PSA that was liberated from the prostate by the procedure (208, 209).
To eliminate in vitro artifacts, blood should be centrifuged within 3 h of collection to isolate the serum or plasma (210). Serum and plasma may be kept at refrigerated temperatures for up to 24 h without loss of PSA. If analysis is delayed longer, then it is vital to store specimens frozen, preferably at or below −30 °C to avoid the eutectic point. Long-term storage at temperatures of at least −70 °C is desirable. Data show that fPSA is more susceptible to loss of immunoreactivity than cPSA (166, 211), and that for fPSA this is slower in plasma than in serum (210).

**NACB PROSTATE CANCER PANEL RECOMMENDATION 7:**
**PREANALYTICAL REQUIREMENTS FOR PSA— PROSTATE MANIPULATION**
Blood should be drawn before any manipulation of the prostate and several weeks after resolution of prostatitis [LOE, not applicable; SOR, A].

**NACB PROSTATE CANCER PANEL RECOMMENDATION 8:**
**PREANALYTICAL REQUIREMENTS FOR PSA— SAMPLE HANDLING**
Samples should be centrifuged and refrigerated within 3 h of phlebotomy; this recommendation is particularly relevant for fPSA, which is more labile than total PSA. Samples may be stored at refrigerated temperatures for up to 24 h, but samples that will not be analyzed within 24 h of collection should be stored frozen (at least at −20 °C and preferably at −30 °C or lower). For long-term storage, samples should be frozen at −70 °C or lower [LOE, not applicable; SOR, B].

**PSA ASSAY STANDARDIZATION**
Two reference standards currently are commonly used for PSA assays: those traceable to the WHO International Standards and those traceable to the Hybritech, Inc. standard. Most clinicians assume that all PSA assays give similar test values and that changes in these test values probably are related to pathophysiological changes in prostate glands. It is assumed that PSA measurements are consistent between laboratories and between assay manufacturers, but this is not necessarily the case (212). Although practice guidelines and disease management strategies vary in terms of what “number” should be used to follow up specific types of patients, these guidelines seldom contain subcategories for various analytical methods.

In practice there are considerable differences between PSA assays. Historically, the Hybritech Tandem-R PSA assay (Hybritech) was the first widely used FDA-cleared commercial assay. This assay was standardized using the absorptivity for PSA of 1.42 mL/mg reported by Graves et al. in 1990 (213). The Hybritech assay was well adopted by the medical community and provided the basis for the traditional 4.0 μg/L upper reference limit (141). The second widely used commercial assay, the Abbott IMx (Abbott Laboratories), was standardized to harmonize with this initial Hybritech assay, and other assays also were closely aligned with these assays (214). However, in 1995, Stamey et al. reported that the mean (SD) true absorptivity for PSA is 1.84 (0.04) mL/mg/cm, based on quantitative amino acid analysis (215). It was suggested that the error in the initial gravimetric analysis was caused by the presence of bound water, salt, or carbohydrate in the lyophilized preparations. The net result of this error is that the initial Hybritech PSA values are about 20% higher than the WHO First International Standard for PSA (IRR 96/670) (216).

The First International Standards for PSA (IRR 96/670) and Free PSA (IRR 96/688) were established in 1999 using the correct absorptivity. The 2 standards contain PSA derived from seminal plasma. IRR 96/670 is a mixture of PSA and ACT in a 90:10 ratio selected to mimic circulating PSA, and IRR 96/688 contains solely free (unbound) PSA. An editorial that accompanied the standardization report, *WHO First International Standards for Prostate-Specific Antigen: The Beginning of the End for Assay Discrepancies*, concluded that this standard would lead to greater consistency of PSA as manufacturers began to use this material to calibrate PSA assays (217). It is now recommended that PSA assays used in the United Kingdom National Health Service must be accurately calibrated against the appropriate International Standard and must be equimolar (218), with formal arrangements in place for independent annual confirmation of satisfactory performance. Although several studies suggest that between-method comparability has improved since introduction of the International Standards, there are still differences in PSA assays that may lead to clinical misinterpretation if different PSA assays are used when evaluating a single patient (218–220).

**ANALYTICAL AND REPORTING CONCERNS**
PSA is most frequently used in conjunction with physical examination to screen for prostate cancer. A single positive PSA screen should always be verified by repeating the PSA measurement in a specimen collected separately, before the ordering of confirmatory histopathological tissue examination, e.g., as obtained by biopsy. This protocol may substantially reduce the number of unnecessary biopsies (221). The diagnosis of prostate cancer can be confirmed only by histopathological tissue examination.

Analytical performance should be monitored with QC material containing PSA at concentrations near
clinically relevant decision points. Information on assay characteristics and utility, including the lowest reportable concentration of the assay (often defined as the PSA concentration below which the analytical CV exceeds 20%) and assay CVs at concentrations corresponding to relevant clinical decision points should be available to clinicians through laboratory test information sources.

**NACB PROSTATE CANCER PANEL RECOMMENDATION 9:**

**ANALYTICAL REQUIREMENTS FOR PSA—QC**

The lowest reportable concentration should be determined by the laboratory and reported to physicians. QC at these concentrations should be in place [LOE, not applicable; SOR, A].

**BIOLICAL VARIABILITY**

To interpret PSA data from any individual or serially collected specimens, PSA variability in the blood should also be taken into account (207, 222). The EGTM recently reviewed publications concerning the variability of PSA and reported that a fair estimate of the biological variation of PSA is 20% in men older than 50 years within the PSA concentration range of 0.1–20 µg/L (223). In healthy men with PSA concentrations <2 µg/L, biological variation was <14%, whereas a change of 30% between successive PSA measurements was suggested to be clinically significant (224). In monitoring men with prostate cancer, a critical difference of 50%–60% has been suggested (225). Taking into account that intraindividual biological variation may range up to 20% and that analytical variation for PSA assays is 5%, it has been suggested that the baseline PSA level has to change by 50% to be significant at P < 0.05 (223).

**NACB PROSTATE CANCER PANEL RECOMMENDATION 10:**

**POSTANALYTICAL REQUIREMENTS FOR PSA—INTRAINDIVIDUAL BIOLOGICAL VARIATION**

The contribution of within-individual biological variation must be taken into account when interpreting clinical results [LOE, not applicable; SOR, A].

It is prudent to include with the PSA result a reminder that a single screening blood test result should not be used as the sole evidence of the presence or absence of malignant disease. The laboratory report should include the manufacturer of the PSA assay used, draw attention to any relevant clinical decision limits, and where necessary warn that the results cannot be used interchangeably with those generated by other assays unless the interchange of assay values has previously been validated (212, 220).

**FUTURE DEVELOPMENTS**

Future developments in the use of tumor markers for prostate cancer include the use of experimental assays to measure circulating tumor cells in blood to detect and assess progression of (micro) metastatic stages of prostate cancer. Assays detecting circulating tumor cells (CTCs) in the peripheral blood have been developed and cleared for clinical use by the FDA to provide prognostic information in women with node-positive breast cancer (226). The current ability to detect and profile (micro) metastatic prostate cancer is limited, however. Multiple techniques have been developed and tested to isolate and characterize CTCs. Reverse transcription PCR assays are sensitive and highly specific when the expression of the target gene is limited to the malignant tumor cells. Flow cytometry can be used to detect and verify the identity of the cells as CTCs, but does not allow assessments of morphology and does not allow detection of molecular changes at a subcellular level. Immobilization (e.g., to magnetic beads) of antibodies to the epithelial cell adhesion molecule allows enrichment and inspection by microscopy of circulating epithelial derived tumor cells from peripheral blood. A semiautomated system was recently developed, which uses epithelial cell adhesion molecule–antibody-based immunomagnetic capture and staining methods (227). Factors predictive of detection of CTCs in prostate cancer have been reported, and for patients with metastatic prostate cancer, the detection of >5 CTCs per 7.5 mL of blood predicts shorter progression-free survival and shorter overall survival, with CTC counts found to be more predictive of outcome than standard clinical parameters (228). For prostate cancer, preliminary analysis of the correlation of CTC counts with mRNAs for prostate specific antigen or prostate specific membrane antigen and available clinical predictors (229) are encouraging but are not yet sufficiently evaluated or validated to warrant recommendations for any use in routine clinical practice.
Disease, with an estimated 154,000 new cases diagnosed in the US, CRC is also the third most common malignant cancer worldwide, with an estimated one million new cases and half a million deaths each year. In the US, CRC is also the third most common malignant disease, with an estimated 154,000 new cases diagnosed in 2007 (118). Most CRC are detected in the rectum (38%), followed by sigmoid (29%), cecum (15%), and transverse colon and flexures (10%). Only approximately 5% are found in the ascending colon and 3% in the descending colon (231).

Symptoms of colon cancer may include intermittent abdominal pain, nausea, vomiting, or bleeding. A palpable mass may be found in patients with right-sided colon cancer. Rectal and rectosigmoid cancer are more likely than colonic cancer to be symptomatic before diagnosis because these patients frequently have rectal bleeding. It is important to point out that early colon cancers are rarely symptomatic and that the above-mentioned symptoms are nonspecific.

Disease stage at initial diagnosis is the most widely used prognostic indicator for patients with CRC. Although the original Dukes staging system has been modified several times, the extent of cancer invasion through the bowel wall and extent of regional lymph node invasion is still the mainstay of staging systems. In practice, the most widely used staging system is the TNM system of the International Union against Cancer (232) and the American Joint Committee on Cancer (233) system. In the TNM system, “T” refers to the local extent of the untreated primary tumor at the time of initial diagnosis. The designation “N” refers to the status of the regional lymph nodes and “M” refers to the presence of distant metastasis at initial presentation (234).

Although surgery is the first-line treatment for most patients with CRC, some patients with rectal cancer may receive radiation and/or chemotherapy before surgery. In 1990, an NIH Consensus Conference recommended that stage III colon cancer patients should be treated with adjuvant chemotherapy (235). A subsequent pooled analysis of patients with stage III CRC confirmed that adjuvant chemotherapy increased both the probability of remaining free of tumor recurrence after 5 years and the probability of surviving for 5 years (236).

The value of adjuvant chemotherapy following resection of stage II (Dukes B) colon cancer is unclear. However, in 2004, an American Society of Clinical Oncology (ASCO) Expert Panel recommended that adjuvant chemotherapy should not, in general, be given to patients with stage II colon cancer (237). However, the panel also stated that “there are populations of patients with stage II disease that could be considered for adjuvant therapy, including patients with inadequately sampled nodes, T4 lesions, perforation, or poorly differentiated histology” (237).

The 1990 NIH Consensus Conference recommended combined adjuvant chemotherapy and high-dose external-beam radiotherapy for patients with stage II or III rectal cancer (235). Although radiation therapy does not appear to affect overall survival, it decreases local recurrence, which is a cause of considerable morbidity in patients with rectal cancer.

Despite potentially curative surgery, 40%–50% of patients with CRC develop recurrent or metastatic disease (238). In an attempt to detect these relapses when they are resectable, most patients with either stage II or stage III disease currently undergo follow-up or surveillance. Surveillance strategies may include one or more of the following: clinical examination, radiology (e.g., chest x-ray, ultrasound, computed tomography, and magnetic resonance imaging), endoscopy, clinical chemistry testing, and the use of tumor markers.

CRC was one of the first cancers in which a tumor marker, i.e., carcinoembryonic antigen (CEA), was used to aid management. We present NACB guidelines on the use of CEA as well as other markers in the detection and management of patients with CRC. In doing so, we also summarize the guidelines from other expert panels on the use of tumor markers in CRC.

To prepare these guidelines, the literature relevant to the use of tumor markers in CRC was reviewed. Particular attention was given to reviews, including systematic reviews, prospective randomized trials that in-

**NACB PROSTATE CANCER PANEL RECOMMENDATION 12:**

**MEASUREMENT OF CIRCULATING PROSTATE CANCER CELLS IN PERIPHERAL BLOOD**

Although initial results are encouraging, these techniques are not yet sufficiently validated to warrant recommending their application in routine clinical practice [LOE, IV; SOR, C].

**KEY POINTS: TUMOR MARKERS IN PROSTATE CANCER**

Measurements of serum PSA markers clearly have an important role in both diagnosis and management of patients with prostate cancer. Further improvement in understanding of the natural history of the disease should enable better use of these markers in the future.

**Tumor Markers in Colorectal Cancer**

**BACKGROUND**

Colorectal cancer (CRC) is the third most common cancer worldwide, with an estimated one million new cases and half a million deaths each year (230). In the US, CRC is also the third most common malignant disease, with an estimated 154,000 new cases diagnosed in 2007 (118). Most CRC are detected in the rectum (38%), followed by sigmoid (29%), cecum (15%), and transverse colon and flexures (10%). Only approximately 5% are found in the ascending colon and 3% in the descending colon (231).

Symptoms of colon cancer may include intermittent abdominal pain, nausea, vomiting, or bleeding. A palpable mass may be found in patients with right-sided colon cancer. Rectal and rectosigmoid cancer are more likely than colonic cancer to be symptomatic before diagnosis because these patients frequently have rectal bleeding. It is important to point out that early colon cancers are rarely symptomatic and that the above-mentioned symptoms are nonspecific.

Disease stage at initial diagnosis is the most widely used prognostic indicator for patients with CRC. Although the original Dukes staging system has been modified several times, the extent of cancer invasion through the bowel wall and extent of regional lymph node invasion is still the mainstay of staging systems. In practice, the most widely used staging system is the TNM system of the International Union against Cancer (232) and the American Joint Committee on Cancer (233) system. In the TNM system, “T” refers to the local extent of the untreated primary tumor at the time of initial diagnosis. The designation “N” refers to the status of the regional lymph nodes and “M” refers to the presence of distant metastasis at initial presentation (234).

Although surgery is the first-line treatment for most patients with CRC, some patients with rectal cancer may receive radiation and/or chemotherapy before surgery. In 1990, an NIH Consensus Conference recommended that stage III colon cancer patients should be treated with adjuvant chemotherapy (235). A subsequent pooled analysis of patients with stage III CRC confirmed that adjuvant chemotherapy increased both the probability of remaining free of tumor recurrence after 5 years and the probability of surviving for 5 years (236).

The value of adjuvant chemotherapy following resection of stage II (Dukes B) colon cancer is unclear. However, in 2004, an American Society of Clinical Oncology (ASCO) Expert Panel recommended that adjuvant chemotherapy should not, in general, be given to patients with stage II colon cancer (237). However, the panel also stated that “there are populations of patients with stage II disease that could be considered for adjuvant therapy, including patients with inadequately sampled nodes, T4 lesions, perforation, or poorly differentiated histology” (237).

The 1990 NIH Consensus Conference recommended combined adjuvant chemotherapy and high-dose external-beam radiotherapy for patients with stage II or III rectal cancer (235). Although radiation therapy does not appear to affect overall survival, it decreases local recurrence, which is a cause of considerable morbidity in patients with rectal cancer.

Despite potentially curative surgery, 40%–50% of patients with CRC develop recurrent or metastatic disease (238). In an attempt to detect these relapses when they are resectable, most patients with either stage II or stage III disease currently undergo follow-up or surveillance. Surveillance strategies may include one or more of the following: clinical examination, radiology (e.g., chest x-ray, ultrasound, computed tomography, and magnetic resonance imaging), endoscopy, clinical chemistry testing, and the use of tumor markers.

CRC was one of the first cancers in which a tumor marker, i.e., carcinoembryonic antigen (CEA), was used to aid management. We present NACB guidelines on the use of CEA as well as other markers in the detection and management of patients with CRC. In doing so, we also summarize the guidelines from other expert panels on the use of tumor markers in CRC.

To prepare these guidelines, the literature relevant to the use of tumor markers in CRC was reviewed. Particular attention was given to reviews, including systematic reviews, prospective randomized trials that in-

cluded the use of markers, and guidelines issued by expert panels. Where possible, the consensus recommendations of the NACB Panel were based on available evidence, i.e., were evidence based.

**CURRENTLY AVAILABLE MARKERS FOR CRC**

The most widely investigated tumor markers for CRC and the phase of development of each marker and the LOE for its clinical use are listed in Table 9.

**TUMOR MARKERS IN CRC: NACB RECOMMENDATIONS**

Table 10 presents a summary of recommendations from representative guidelines published on the use of tumor markers in CRC. This table also summarizes the NACB guidelines for the use of markers in this malignancy. Below, we present a more detailed discussion of the most widely investigated markers listed in Table 10.

**CARCINOEMBRYONIC ANTIGEN**

**CEA in screening.** Lack of sensitivity and specificity when combined with the low prevalence of CRC in asymptomatic populations preclude the use of CEA in screening for CRC (239–241). In agreement with ASCO (242–244) and EGTM recommendations (245, 246), the NACB Panel states that CEA cannot be used in screening healthy individuals for early CRC.

**CEA in determining prognosis.** As mentioned above, disease stage at initial diagnosis is universally used to determine prognosis in patients with CRC. Several studies, however, have demonstrated that preoperative concentrations of CEA can also provide prognostic information, which in some situations was found to be independent of stage (239–241, 247–249). The NACB Panel therefore states that preoperative concentrations of CEA might be used in combination with other factors in planning surgical treatment. Preoperative CEA concentrations, however, should not be used at present to select patients for adjuvant therapy. These guidelines are broadly in agreement with those previously published by ASCO and EGTM (242, 244–246).

A College of American Pathologists Expert Panel recently ranked preoperative serum CEA together with TNM stage, regional lymph node metastasis, blood or lymphatic vessel invasion, and residual tumor following surgery with curative intent as a category I prognostic marker for CRC (250). According to the College of American Pathologists Panel, Category I prognostic factors are those “definitely proven to be of prognostic importance based on evidence from multiple statistically robust published trials and generally used in patient management”.

**CEA in postoperative surveillance.** The main aims of surveillance following curative resection of CRC are to provide reassurance, address possible complications due to therapy, and identify resectable recurrences or metastases. Six separate metaanalyses have compared outcome in patients with intensive follow-up vs those with minimal or no follow-up (251–256). All concluded that the use of an intensive follow-up regime resulted in a modest but statistically significant improved outcome when compared with regimes with minimal follow-up. In one of these metaanalyses, it was shown that only the studies including CEA demonstrated a significant impact on survival (254).

The most recent ASCO guidelines state that CEA should be measured every 3 months in patients with stage II or III CRC for at least 3 years after diagnosis, if the patient is a candidate for surgery or systemic therapy of metastatic disease (244, 257). The NACB Panel supports this recommendation.

Although serial measurements of CEA are widely used in surveillance, no agreement exists as to the magnitude of concentration change that constitutes a clinically significant increase in CEA during serial monitoring. According to the EGTM Panel, a significant increase in CEA occurs if the elevation is at least 30% over that of the previous value. This increase, however, must be confirmed by a second sample taken within 1 month. If this latter sample is also increased, the patient should undergo further investigations (246). This 30% increase, however, has not been clinically validated. Furthermore, it should not be regarded as exclusive. For example, small increases in CEA (e.g., 15%–20%, maintained over at least 3 successive assays) may also prompt intervention (246). It should also be remembered that low CEA concentrations do not necessarily exclude progression, and in patients with clinical

symptoms of disease recurrence, additional tests such as computed tomographic scan, x-rays, and colonoscopy are required, irrespective of the CEA concentration (246).

**CEA in monitoring therapy in advanced disease.** The prognosis for patients with advanced CRC has greatly improved in recent years owing to the introduction of new cytotoxic agents such as irinotecan and oxaliplatin and monoclonal antibodies such as bevacizumab (Avastin®), panitumumab (Vectibix®), and cetuximab (Erlotinib®), as has recently been reviewed (258, 259). Indeed, the median survival for patients with metastatic CRC has almost doubled in the past 10 years as a result of these new treatments (258–260). However, because these treatments are potentially toxic as well as expensive, it is important to establish as quickly as possible that they are effective in halting tumor progression.

According to the 2006 ASCO guidelines, CEA is the marker of choice for monitoring metastatic CRC during systemic therapy (244). CEA should be measured at the start of treatment for metastatic disease and every 1–3 months during active treatment. Persistently increasing concentrations suggest progressive disease even in the absence of corroborating radiographs (242, 243). In 2003, the EGTM Panel recommended that serial CEA concentrations should be measured every 2–3 months while patients are receiving systemic therapy (246). Both the ASCO and EGTM guidelines stated that caution should be used when interpreting increasing CEA concentrations during the early phase of systemic treatment (16, 18). This is because certain treatments (e.g., 5-fluorouracil and levamisole; oxaliplatin) can cause transient elevations in CEA levels in the absence of disease progression (246).

For monitoring patients with advanced CRC undergoing systemic therapy, the NACB Panel recommends that regular CEA determinations should be carried out. In agreement with the ASCO Panel (242, 243), a confirmed CEA increase (e.g., >30%) may be regarded as evidence of progressive disease. Of course, it should be established that the increases are not false-positive elevations due to either chemotherapy-mediated release of marker or the development of a benign disease that produces CEA.

**NACB CRC PANEL RECOMMENDATION 3: SERUM CEA IN POSTOPERATIVE SURVEILLANCE**

CEA should be measured every 3 months in patients with stage II or III CRC for at least 3 years after diagnosis if the patient is a candidate for surgery or systemic therapy of metastatic disease [LOE, I; SOR, A].

**NACB CRC PANEL RECOMMENDATION 4: SERUM CEA IN MONITORING PATIENTS WITH ADVANCED DISEASE**

In patients with advanced CRC undergoing systemic therapy, regular CEA determinations should be carried out. A confirmed CEA increase (e.g., >30%) suggests progressive disease provided the possibility of false-positive elevations can be excluded [LOE, III; SOR, B].

**OTHER SERUM MARKERS**

CA 19–9. The CA 19–9 assay detects a mucin containing the sialated Lewis-a pentasacharide epitope, fucopentaose II [for review, see ref (261)]. CA 19–9 is a less sensitive marker than CEA for CRC (262, 263). Preliminary findings suggest that like CEA, preoperative concentrations of CA 19–9 are also prognostic in patients with CRC (264–268). Based on available data, routine measurement of CA 19–9 cannot be recommended for patients with CRC.

CA 242. The CA 242 assay also detects a mucinlike molecule. Although less sensitive than CEA for CRC, assay of CA 242 may complement CEA in the surveillance of patients with CRC (263, 269). Furthermore, a number of preliminary reports suggest that preoperative concentrations of CA 242 are prognostic in CRC (270, 271). Routine determinations of CA 242 should not be used at present in patients with CRC.

**TISSUE INHIBITOR OF METALLOPROTEINASES TYPE 1**

Tissue inhibitor of metalloproteinases type 1 (TIMP-1) is a 25-kDa glycoprotein with multiple activities including inhibition of matrix metalloproteinases, promotion of cell proliferation, and inhibition of apoptosis. With use of a research ELISA that detects total TIMP-1 (i.e., the noncomplex form as well as TIMP-1 complexed to matrix metalloproteinases), plasma concentrations of the inhibitor were found to be significantly higher in patients with CRC than in healthy controls or patients with inflammatory bowel diseases, adenomas, or breast cancer (272, 273). For patients with Dukes A and B colon cancers, TIMP-1 appeared to be more sensitive than CEA for the detection of cancer, i.e., 58% vs 40% at 95% specificity and 56% vs 30% at 98% specificity. For patients with early rectal cancer, TIMP-1 and CEA had similar sensitivity (272). Other studies have shown that preoperative plasma TIMP-1 concentration is an independent prognostic factor in patients with CRC, i.e., independent of Dukes stage and tumor location (274, 275). Of particular note was the finding that stage II patients with low plasma TIMP-1 concentrations (dichotomized at the 70% per-
centile) exhibited a survival pattern similar to an age and sex-matched background population.

Although these preliminary findings with TIMP-1 are promising, the marker cannot be recommended at present either for detecting early CRC or for evaluating prognosis in patients with this malignancy.

**NACB CRC PANEL RECOMMENDATION 5:**
**CA19.9, CA 242 AND TIMP-1 IN CRC**
Routine measurement of CA19.9, CA 242, or TIMP-1 is not recommended [LOE, III/IV; SOR, B/C].

**TISSUE MARKERS**
Several tumor tissue markers have been evaluated for potential prognostic and predictive value in patients with CRC. These include thymidylate synthase (276–280), MSI (281–285), deleted in colon cancer (286–288), urokinase plasminogen activator (uPA)/plasminogen activator inhibitor 1 (PAI-1) (289–291), mutant ras (292), and mutant/overexpression of p53 (293). Based on available evidence, none of these markers can at present be recommended for routinely determining prognosis or for therapy prediction. Emerging evidence however, suggests that the presence of wild type k-ras is associated with benefit from the anti–epidermal growth-factor receptor (EGFR) antibodies cetuximab and panitumumab (294–297).

**NACB CRC PANEL RECOMMENDATION 6:**
**TISSUE MARKERS IN CRC**
The use of thymidylate synthase, MSI, deleted in colon cancer, uPA, PAI-1, or p53 for determining prognosis or predicting response to therapy is not recommended [LOE, III; SOR, B]. Determination of the mutation status of k-ras may in the future be used for predicting benefit from specific anti-EGFR antibodies.

**Fecal Markers**
The most widely used fecal marker involves testing for occult blood, i.e., the fecal occult blood test (FOBT). Two of the most widely described FOBTs are the guaiac test and the fecal immunochemical test (FIT) (298–301). The guaiac test measures the pseudoperoxidase activity of heme in hemoglobin, and the immunochemical test detects human globin. Because peroxidase activity is also present in certain fruits and vegetables, intake of these foods may give rise to false-positive results in the guaiac test. Certain medicines such as nonsteroidal antiinflammatory drugs can also interfere with this test. Despite these limitations, a number of large randomized trials have shown that screening with the guaiac test reduced mortality from CRC (302–306).

The efficacy of the FIT in reducing either the incidence or mortality from CRC has not yet been investigated in large population-based studies. However, based on available evidence, it should be at least as accurate if not more accurate than guaiac-based tests in screening for CRC (298, 301, 307). The advantages of the immunochemical test over the guaiac tests include the following (for review, see refs 298, 299, 307):

- FITs have better sensitivity for human blood.
- FITs are not affected by diet or medications.
- Some FITs can be automated.
- Evidence suggests that the use of FITs increases patient participation in screening for CRC.
- FITs can be quantitated, enabling adjustment of sensitivity, specificity and positivity rates.
- Because digested blood from the upper gastrointestinal tract is not usually detected by FITs, the latter are better for detecting bleeding from the lower gastrointestinal tract.

In agreement with other expert panels (308–310), the NACB Panel recommends that all individuals 50 years or older should undergo screening for CRC. Multiple screening procedures for CRC exist, however (306–308), and to date no one procedure has been shown to be significantly superior to the others. The option chosen may therefore depend on availability, personal preference, and risk of developing CRC (311).

According to the National Comprehensive Cancer Network (NCCN), FOBT should be performed on 3 successive stool specimens that are obtained while the patient adheres to a prescribed diet (308). This organization specifically recommends the Hemoccult SENSA as the testing method. Both the NCCN and the American Cancer Society recommend against use of FOBT of a specimen obtained during a digital rectal examination (308, 311).

Although screening has been shown to result in reduced mortality from CRC (302–305, 312), it may be associated with certain harmful effects. These include the psychosocial consequence of false-positive results, potential complications of colonoscopy, a false-negative result, or the possibility of over-diagnosis (312). Overdiagnosis could give rise to unnecessary investigations or treatment.

Because of the lack of sensitivity and specificity of FOBT for adenomas and early CRC, a considerable amount of research in recent years has focused on other fecal markers, especially on the genes that undergo mutation during CRC carcinogenesis. Among the most widely investigated DNA markers are mutant ras, mutant p53, mutant APC, specific methylated genes, MSI, and long DNA (231, 313–316). Almost all of
the studies published to date on fecal DNA markers contained small numbers of patients. Following an overview of the literature, Allison and Lawson (298) found that the sensitivities of the different DNA panels for invasive CRC varied from 52%–98% (mean, 64%), and the specificity varied from 93%–97% (mean, 95%).

Although most of the studies that evaluated DNA markers for the detection of CRC included only small numbers of patients, a specific panel was recently investigated as a screening test for CRC in a large asymptomatic population (317). Of the 31 invasive CRCs detected, the DNA panel diagnosed 16, whereas FOBT detected only 4 (51.6% vs 12.9%, \(P = 0.003\)). Of the 71 invasive cancers and adenomas with high-grade dysplasia, the DNA panel diagnosed 29, while FOBT detected only 10 (\(P < 0.001\)). Although the DNA panel displayed a higher sensitivity than FOBT, clearly neither test detected the majority of advanced adenomas or carcinomas (317). However, because the DNA-based test was superior to FOBT, it might be expected to be at least as good as the latter in reducing mortality from CRC. However, it should be pointed out that compared to FOBTs, measurement of fecal DNA markers is more expensive and technically demanding. Furthermore, it is not clear which combination of DNA markers provides the optimum balance of sensitivity and specificity (231).

One of the main arguments against the use of a DNA panel at present, especially when applied to large populations, is the relative cost compared to FOBT (318, 319). In 2004, Song et al. (318), using a modeling approach, compared the cost-effectiveness of fecal DNA to that of standard CRC screening methods. The main conclusions were as follows:

- Compared with no screening, all screening strategies increased life expectancy at what was regarded as reasonable cost.
- Compared with no screening, the use of fecal DNA testing gained 4560 life-years per 100 000 persons at an incremental cost of $47 700/life-year gained.
- The use of colonoscopy and FOBT/flexible sigmoidoscopy were more effective strategies, gaining an incremental 6190 and 6270 life-years per 100 000 persons compared to no screening, at incremental costs per life-year gained of $17 010 and $17 000.
- All the conventional approaches gained more life-years at lower cost than fecal DNA testing.

Despite their relatively high costs, the technically demanding nature of the assays, and the fact that these tests have not been validated in a prospective randomized trial, recent joint guidelines from the American Cancer Society, the US Multi-Society Task Force, and the American College of Radiology state that there is now sufficient data to include fecal DNA “as an acceptable option for CRC screening” (320, 321).

**NACB CRC PANEL RECOMMENDATION 7:**
**USE OF FECAL MARKERS IN SCREENING FOR CRC**
The NACB recommends that all individuals 50 years or older should undergo screening for CRC. Because the most effective screening test is unknown, the method chosen is likely to depend on risk of CRC, local availability, and personal preference. Although FOBT is the best-validated stool-based method for screening for CRC [LOE, I; SOR, A], fecal DNA testing may also be an option. Potential harmful consequences of screening include complications due to colonoscopy and treatment, the possibility of overdiagnosis leading to unnecessary investigations, and false-negative and false-positive results.

**GENETIC TESTS**
For genetic testing for CRC susceptibility, i.e., familial adenomatous polyposis coli and hereditary nonpolyposis CRC, the NACB Panel supports previously published guidelines (308, 322–326).

**NACB CRC PANEL RECOMMENDATION 8:**
**GENETIC TESTING FOR CRC**
Screening for genetic susceptibility to CRC should commence with a detailed family history. Before undergoing testing, individuals should receive genetic counseling. For persons with suspected familial adenomatous polyposis, genetic testing can be used both to confirm diagnosis in a suspected proband and to assess risk in presymptomatic family members. Provided the mutation responsible for familial adenomatous polyposis within a family is known, testing for adenomatous polyposis coli (APC) gene mutations can be considered for at-risk family members. [LOE, Expert opinion; SOR, A].

MSI testing and/or immunohistochemistry for specific mismatch repair enzymes can be used as a prescreen for hereditary nonpolyposis CRC. If an individual is found to possess high MSI, genetic testing for mutations in MLH1, MLH2, MSH6, or PMS2 genes should be carried out [LOE, III/IV; SOR, A].

---

23 MLH1, mutL homolog 1, colon cancer, nonpolyposis type 2 (E. coli); MSH2, mutS homolog 2, colon cancer, nonpolyposis type 1 (E. coli); MSH6, mutS homolog 6 (E. coli); PMS2, postmeiotic segregation increased 2 (S. cerevisiae).
KEY POINTS: TUMOR MARKERS IN CRC
Although many different markers have been evaluated for CRC, only a small number can be recommended for clinical use. These include CEA in the postoperative surveillance of patients who may be suitable candidates for either surgical resection or systemic chemotherapy, FOBT in screening for early CRC in persons 50 years or older, MSI as a surrogate marker for identifying persons who should undergo genetic testing for MLH1/MSH2/MSH6/PMS2 to identify hereditary nonpolyposis CRC, and APC to identify familial adenomatous polyposis. A promising new plasma marker is TIMP-1. As mentioned above, preliminary findings suggest that this marker may be more sensitive than CEA in detecting early CRC as well as being an independent prognostic factor for CRC. These findings now must be confirmed in large prospective studies. One of the most promising fecal CRC screening tests is a fecal DNA panel (317). This test should be simplified, made available at reduced costs, and subjected to further investigations.

Tumor Markers in Breast Cancer

BACKGROUND
Breast cancer is by far the most common cancer affecting women worldwide, with approximately one million new cases diagnosed each year (327). In 2007, an estimated 180,000 women were diagnosed with breast cancer in the US and approximately 41,000 died from the disease (118). Currently, there are more than 2 million women in the US who are living with a history of breast cancer (328). Although the worldwide incidence of the disease appears to be increasing, mortality rates are now declining in a number of Western countries including the US and the United Kingdom (329).

The main presenting features in women with symptomatic breast cancer include a lump in the breast, nipple change, or discharge and skin contour changes. Definitive diagnosis requires biopsy and histopathology. Currently available blood-based biomarkers are of no value in the early diagnosis of breast cancer.

The primary treatment for localized breast cancer is either breast-conserving surgery and radiation or mastectomy. Following primary treatment, most women with invasive breast cancer receive systemic adjuvant therapy such as chemotherapy, hormone therapy, or a combination of chemotherapy and hormone therapy. Both adjuvant chemotherapy and hormone therapy have been shown to reduce systemic recurrence and mortality from breast cancer (330). For example, a meta-analysis of approximately 145,000 women participating in 194 randomized trials of adjuvant systemic therapy concluded that anthracycline-based polychemotherapy reduced the annual breast cancer death rate by about 38% for women younger than 50 years at diagnosis and by about 20% for those age 50–69 years at diagnosis (330). For estrogen receptor (ER)-positive patients, 5 years of adjuvant tamoxifen reduced annual breast cancer death rates by 31% (330). Patients with ER-negative tumors, however, did not benefit from adjuvant tamoxifen (331).

Because not all patients with breast cancer may need adjuvant treatment [e.g., approximately, 70% of lymph node–negative patients are cured of their disease by surgery and radiotherapy (332)] and not all patients benefit from this treatment, rational management requires the availability of reliable prognostic and predictive markers. Recommendations regarding the use of currently available prognostic and predictive markers for breast cancer are discussed below.

Subsequent to primary therapy, patients with a diagnosis of breast cancer are usually followed up at regular intervals. Historically, surveillance has included clinical history, physical examination, mammography, chest x-ray, biochemical testing, and the use of tumor markers. This practice is based on the assumption that the early detection of recurrent disease leads to a better outcome. However, at present, the clinical benefit of close surveillance is unclear (333).

Although adjuvant therapy improves patient outcome, 25%–30% of women with lymph node–negative and at least 50%–60% of those with node-positive disease develop recurrent or metastatic disease (334). Therapy options for metastatic breast cancer include chemotherapy (e.g., anthracycline or taxane-based), hormone therapy, or targeted therapies such as Trastuzumab (Herceptin®), Lapatinib, or Bevacizumab, alone or combined with chemotherapy (334, 335). Currently, metastatic breast cancer is regarded as incurable and thus the goal of treatment is generally palliative. In this context, the use of serial levels of serum tumor markers is potentially useful in deciding whether to persist in using a particular type of therapy, terminate its use, or switch to an alternative therapy.

Based on the above, it is clear that optimal management of patients with breast cancer requires the use of a number of tumor markers. The aim of this article is to present new NACB guidelines on the use of both tissue- and serum-based tumor markers in breast cancer. A summary of guidelines published by other expert panels on this topic is also provided.

---

34 NACB Breast Cancer Sub-Committee Members: Michael J. Duffy, Chair; Francisco J. Esteva; Nadia Harbeck; Daniel F. Hayes; and Rafael Molina.
35 All comments received about the NACB Recommendations for Breast Cancer are included in the online Data Supplement. Professor Dorte Nielsen, Professor John Smyth, and Professor M. Tuxen were invited expert reviewers.

Clinical Chemistry 54:12 (2008) e43
To prepare these guidelines, the literature relevant to the use of tumor markers in breast cancer was reviewed. Particular attention was given to reviews, including systematic reviews, prospective randomized trials that included the use of markers, and guidelines issued by expert panels. Where possible, the consensus recommendations of the NACB Panel were based on available evidence, i.e., were evidence-based.

CURRENTLY AVAILABLE MARKERS FOR BREAST CANCER

Table 11 lists the mostly widely investigated tissue-based and serum-based tumors markers for breast cancer. Also listed, is the phase of development of each marker as well as the LOE for its clinical use.

TUMOR MARKERS IN BREAST CANCER: NACB RECOMMENDATIONS

Table 12 presents a summary of recommendations from various expert panels on the use of tumor markers in breast cancer. This table also summarises the NACB guidelines for the use of markers in this malignancy. Below, we present a more detailed discussion on the most clinically useful markers listed in Table 12.

ER and progesterone receptor. Routine assay of ERs (i.e., ER-α) and progesterone receptors (PR) in all newly diagnosed breast cancers has been recommended by Expert Panels of ASCO, EGTM, the European Society of Medical Oncology, and the St Gallen Conference Consensus Panel (Table 12). The NACB Panel agrees with these recommendations. The primary purpose of determining ER and PR is to select for likely response to endocrine therapy in patients with either early or advanced breast cancer. Additionally, in combination with other factors, ER and PR may also be used for prognostic purposes. However, as predictors of patient outcome, hormone receptors are relatively weak factors and are of little clinical value in lymph node–negative patients. Hormone receptors should therefore not be used alone for determining outcome in breast cancer. However, in combination with established prognostic factors, hormone receptors may be used to predict risk of recurrence. Determination of ER-β has no clinical application at present.

Recommended assays for ER and PR. ER (i.e., ER-α) and PR can be measured by ligand-binding assay, ELISA, or immunohistochemistry. The advantages and disadvantages of these different assays are summarized in Table 13. It is important to note that most of the clinical data relating to both ER and PR were derived from biochemical (ligand-binding and ELISA) assays. Some recent investigations, however, have shown that the immunohistochemical determination of ER provides clinical information at least as powerful as that obtained with the biochemical assays (336–341). Indeed, one report stated that the use of immunohistochemistry to determine ER was superior to that of biochemical assays for predicting response to therapy (336). Compared to ER, fewer data are available on the clinical value of PR as determined by immunohistochemistry (341–343). As with ER, the predictive power of PR as determined by immunohistochemistry appears to be superior to that obtained using ligand-binding assays (343).

Because of its ease of use and application to a wider range of tumors (e.g., small as well as large tumors and paraffin-embedded as well as frozen tissue), the NACB Panel recommends the use of immunohistochemistry for the determination of both ER and PR.

The following points should be borne in mind when determining ER and PR by immunohistochemistry:

- Immunohistochemical assays used should have been shown to give values that correlate with biochemical assays and should be validated for both predictive and prognostic purposes. Validated antibodies include 6F11 MAb (Novocastra) or antibody ID5 (Dako) for ER and antibody 1A6 (Novocastra), PR88 (Biogenex, Menarini Diagnostics) or monoclonal antibody 1294 (Dako) for PR (336, 337, 343–345).
- Internal controls should be included in each examination. A tissue control with receptor-positive cancer cells and adjacent benign epithelium has been previously recommended (345).
- Participation in an external quality assessment scheme is essential (344, 345).
- Scoring of stain may be based either on percentage of cells stained or on a combination of percentage of cells stained plus intensity of stain. A semiquantitative score should be reported rather than a negative or positive value (344, 345). It is important to state that patients with low ER levels (e.g., staining in 1%–10% of the cells) have been reported to respond to endocrine therapy (336).
- Only nuclear staining should be evaluated.
- The report should mention source of primary antibody as well as type of tissue used (e.g., paraffin-embedded or frozen) (345).

NACB BREAST CANCER PANEL RECOMMENDATION 1:

**ER AND PR AS PREDICTIVE AND PROGNOSTIC MARKERS**

ER and PR should be measured in all patients with breast cancer. The primary purpose of measuring these receptors is to identify patients with breast cancer that can be treated with hormone therapy [LOE, I; SOR, A].

Continued on page e47
In combination with established prognostic factors, i.e., tumor stage, tumor grade, and number of lymph node metastases, ER and PR may also be used for determining short-term prognosis in patients with newly diagnosed breast cancer [LOE, III; SOR, B]. HER-2 gene. In agreement with the ASCO (243), joint ASCO/College of American Pathologists (346), and NCCN Panels (347), the NACB Panel also recommends determination of the gene HER-2[36] on all newly diagnosed patients with invasive breast cancers (Table 12). At present, the primary purpose for determining HER-2 is to select patients who may be treated with Trastuzumab in either early or advanced breast cancer. In combination with other factors, HER-2 may also be used to determine prognosis. Insufficient data are currently available to recommend HER-2 for predicting response either to adjuvant endocrine therapy or to cyclophosphamide, methotrexate and 5-fluorouracil-based adjuvant chemotherapy (243, 348–351). HER-2, however, may be used to predict the superiority of anthracycline-based adjuvant chemotherapy over methotrexate and 5-fluorouracil–based adjuvant chemotherapy (243, 348–350, 352). Insufficient data are presently available to recommend routine use of serum HER-2 testing. Preliminary findings, however, suggest that serum HER-2 may be of value in monitoring patients with advanced breast cancer undergoing treatment with Trastuzumab (353).

**Recommended assays for HER-2.** Two main types of assay are used to detect HER-2 in breast tumors, i.e., immunohistochemical analysis (IHC) and FISH (354–360). The advantages and disadvantages of these methods are summarized in Table 14 (354–360).

b SOR (520), A, high (further research is very unlikely to change the panel’s confidence in the estimate of effect); B, moderate (further research is likely to have an important impact on the panel’s confidence in the estimate of effect and is likely to change the estimate); C, low (further research is very likely to have an important effect on the panel’s confidence in the estimate of effect and is likely to change the estimate); D, very low (any estimate of effect is very uncertain).

c Recommendations state tumor markers without referring to specific markers.
Following a systematic review of the literature, a joint ASCO/College of American Pathologists panel recently published comprehensive guidelines for HER-2 testing in patients with invasive breast cancer (346). Some of the key conclusions are as follows:

- As presently performed, approximately 20% of HER-2 testing may be inaccurate.
- When properly validated assays are used, existing data does not clearly show a superiority for either IHC or FISH for predicting response to Trastuzumab. HER-2 should be measured on the invasive component of the breast cancer.
- Laboratories performing HER-2 assays should show at least 95% concordance with another validated test.
- Validation of assays or modifications, the use of standard operating procedures, and compliance with new testing criteria should be monitored by using stringent laboratory accreditation standards, proficiency testing, and competency (346).

The ASCO/College of American Pathologists panel recommended the following algorithm for defining HER-2 status:

- HER-2 positivity was defined as IHC staining of 3+ (uniform and intense membrane staining of >30% of invasive cancer cells), a FISH value >6 HER-2 gene copies per nucleus or a FISH ratio (HER-2:CEP 17) of >2.2 (CEP, centromeric probe for chromosome 17).
- HER-2 negativity was defined as an IHC score of 0 or 1+, a FISH value of <4 HER-2 gene copies per nucleus or a FISH ratio of <1.8.
- HER-2 IHC was regarded to be equivocal with a score of 2+, i.e., complete membrane staining that is either nonuniform or weak in intensity but with clear circumferential distribution in at least 10% of cells. The equivocal range for FISH was an HER-2:CEP 17 ratio from 1.8–2.2 or an average gene copy number from 4.0–6.0 for those assays without an internal probe. For samples with equivocal IHC scores, FISH should be performed. For samples with equivocal FISH results, the test should be either repeated or additional cells counted.

The NACB Panel supports the above recommendations.

Currently, the FDA has approved a number of assays for detecting HER-2 in breast cancer. Two of these assays are based on immunohistochemistry (Dako and Ventana Medical Systems) and 2 on FISH (Ventana...
Medical Systems and Vysis Inc). Both IHC assays were originally approved for identifying women with advanced breast cancer for therapy with Trastuzumab. The FISH-based tests were originally cleared for the selection of women with node-negative disease at high risk for progression and for response to doxorubicin-based therapy. More recently, these tests have also been approved for selecting women with metastatic breast cancer for treatment with Trastuzumab. In 2008, the FDA gave premarket clearance for a new chromogenic in situ hybridization (CISH) assay (Invitrogen) for identifying patients eligible for Trastuzumab. A serum-based-HER-2 test has been cleared by the FDA for follow-up and monitoring patients with advanced breast cancer (Siemens Healthcare Diagnostics).

* Data summarized from refs (354–360).

**NACB BREAST CANCER PANEL RECOMMENDATION 2:**

**HER-2 as a Predictive and Prognostic Marker**

HER-2 should be measured in all patients with invasive breast cancer. The primary purpose of measuring HER-2 is to select patients with breast cancer that may be treated with Trastuzumab [LOE, I; SOR, A].

HER-2 may also identify patients that preferentially benefit from anthracycline-based adjuvant chemotherapy [LOE, II/III; SOR, B].

*uPA and PAI-1.* Results from a pooled analysis comprising more than 8000 patients have shown that both uPA and PAI-1 are strong (relative risk >2) and independent (i.e., independent of nodal metastases, tumor size, and hormone receptor status) prognostic factors in breast cancer (361). For axillary node–negative patients, the prognostic impact of these 2 proteins has been validated by use of both a randomized prospective trial (Chemo N0 study) and a pooled analysis of small-scale retrospective and prospective studies (361, 362). uPA and PAI-1 are thus the first biological factors in breast cancer to have their prognostic value validated by using level 1–evidence studies (363).

The NACB Panel therefore states that testing for uPA and PAI-1 may be carried out to identify lymph node–negative patients who do not need or are unlikely to benefit from adjuvant chemotherapy. Measurement of both proteins should be performed because the information provided by the combination is superior to that from either alone (361, 364). Lymph node–negative patients with low levels of both uPA and PAI-1 have a low risk of disease relapse and thus may be spared from the toxic side effects and costs of adjuvant chemotherapy. Lymph node–negative women with high levels of either uPA or PAI-1 should be treated with adjuvant chemotherapy. Indeed, results from the Chemo N0 trial (362) as well as data from recent large retrospective studies (364, 365) suggest that patients with high levels of uPA/PAI-1 derive an enhanced benefit from adjuvant chemotherapy.

**Recommended assays for uPA and PAI-1.** Measurement of both uPA and PAI-1 should be carried out using a
valid ELISA. A number of ELISAs have undergone technical validation (366), and some have also been evaluated in an external quality assessment scheme (367). For determining prognosis in breast cancer, the NACB Panel recommends use of an ELISA that has been both technically and clinically validated (e.g., from American Diagnostic). Extraction of tumor tissue with Triton X-100 is recommended (368). It is important to note that to perform an ELISA for uPA or PAI-1, a representative piece of fresh (i.e., not fixed in formalin) breast tumor (>200–300 mg) must be stored in liquid nitrogen immediately after histological diagnosis.

Recently, a microassay using as little as 100 mg of tumor tissue was described for the measurement of uPA and PAI-1 (369, 370). This assay can also use material from 2 or 3 core biopsies or from 5–10 90-μm-thick cryosections. Although not yet clinically validated, preliminary data showed that uPA and PAI-1 levels in core biopsies correlated well with corresponding levels in surgically removed tissue. Because IHC thick cryosections. Although not yet clinically validated, this method cannot be recommended, at present, for the routine determination of these proteins in breast cancer.

NACB BREAST CANCER PANEL RECOMMENDATION 3: uPA AND PAI-1 FOR DETERMINING PROGNOSIS

uPA and PAI-1 may be used to identify lymph node–negative breast cancer patients who do not need or are unlikely to benefit from adjuvant chemotherapy. uPA and PAI-1 should be measured by a validated ELISA using extracts of fresh or freshly frozen tumor [LOE, I; SOR, A].

CA 15-3/BR 27.29. The CA 15-3 and BR 27.29 (also known as CA 27.29) serum assays detect the same antigen, i.e., MUC1 protein, and provide similar clinical information. CA 15-3 has, however, been more widely investigated than BR 27.29. There are conflicting views about the value of CA 15-3 and BR 27.29 in the postoperative surveillance of asymptomatic patients who have undergone curative surgery for breast cancer (15, 242, 243, 371–375). Although increasing CA 15-3 or BR 27.29 levels can preclinically detect distant metastatic disease in approximately 70% of asymptomatic patients, there is no high-level evidence study showing that the early diagnosis of progressive disease followed by initiation of therapy positively impacts either patient survival or quality of life. Furthermore, there is no universally accepted or clinically validated definition of a clinically significant tumor marker increase. A confirmed increase of at least 25% however, is widely interpreted to signify a clinically significant increase.

Based on current evidence, the NACB Panel recommends against routine CA 15-3 (or BR 27.29) testing in asymptomatic patients following diagnosis of operable breast cancer. The Panel, however, would like to note that there are a number of small studies suggesting that the early initiation of therapy based on increasing serum markers levels can lead to an enhanced outcome (376–378). Although these studies do not provide high-level evidence that early treatment based on rising tumor marker levels positively impacts on patient outcome, some doctors as well as some patients may wish to have serial levels of CA 15-3 (or BR 27.29) determined following primary surgery. The ultimate decision about whether or not to use CA 15-3 (BR 27.29) in this situation must be made by the doctor in consultation with the patient.

According to both ASCO and NCCN, CA 15-3 (or BR 27.29) should not be used alone for monitoring therapy in advanced disease (242, 243, 347, 375). The EGTM Panel recommends that in patients with metastatic disease, markers should be determined before each course of chemotherapy and at least every 3 months for patients receiving hormone therapy (371).

The NACB Panel states that CA 15-3 or BR 27.29 in combination with imaging and clinical examination may be used to monitor chemotheraphy in patients with advanced breast cancer. These markers may be particularly helpful in patients with non-evaluable disease. In such patients, 2 successive increases (e.g., each >30%) are likely to indicate progressive disease and may result in cessation of therapy, change in therapy, or entry of the patient into clinical trials evaluating new anticancer treatments. However, as with markers during postoperative surveillance, there is no universally accepted or clinically validated definition of a clinically significant increase in marker concentration during therapy of advanced disease.

It is important to bear in mind that following the initiation of chemotherapy, a transient increase in serum marker levels may occur (379, 380). Such transient increases or spikes usually subside within 6–12 weeks after starting chemotherapy. Increases in marker levels unrelated to tumor progression might also occur as a result of certain benign diseases (381). These increases may be transient or progressive depending on whether the benign disease is short-lived or continues to deteriorate.

Recommended assays for CA 15-3/BR 27.29. The FDA has cleared a number of commercially available CA 15-3 and BR 27.29 assays.
**NACB BREAST CANCER PANEL RECOMMENDATION 4:**

**CA 15-3 AND BR 27.29 IN POSTOPERATIVE SURVEILLANCE AND MONITORING THERAPY IN ADVANCED DISEASE**

CA 15-3 and BR 27.29 should not be routinely used for the early detection of recurrences/metastases in asymptomatic patients with diagnosed breast cancer. However, because some patients, as well as some doctors, may wish to have these measurements, the ultimate decision on whether or not to use CA 15-3 or BR 27.29 must be made by the doctor in consultation with the patient [LOE, III; SOR, B].

In combination with radiology and clinical examination, CA 15-3 or BR 27.29 may be used to monitor chemotherapy in patients with advanced breast cancer. For patients with nonevaluable disease, sustained increases in marker concentrations suggest progressive disease [LOE, III; SOR, B].

**Recommended assay for CEA.** The FDA has cleared a number of commercially available CEA assays.

*Carinoembryonic antigen.* As for CA 15-3 and BR 27.29, the NACB Panel does not recommend routine use of CEA in the surveillance of patients with diagnosed breast cancer. For monitoring patients with advanced disease, CEA should not be used alone. For monitoring patients with nonevaluable disease, CEA may occasionally be informative when CA 15-3/BR 27.29 is not. As a marker for breast cancer, CEA is generally less sensitive than CA 15-3/BR 27.29, but on occasion, CEA can be informative when levels of MUC-1-related markers remain below the cutoff point.

**NACB BREAST CANCER PANEL RECOMMENDATION 3:**

**CEA IN POSTOPERATIVE SURVEILLANCE AND MONITORING OF THERAPY IN ADVANCED DISEASE**

CEA should not be routinely used for the early detection of recurrences/metastases in patients with diagnosed breast cancer. However, because some patients as well as some doctors may wish to have these measurements, the ultimate decision on whether or not to use CEA must be made by the doctor in consultation with the patient [LOE, III; SOR, B].

In conjunction with radiology and clinical examination, CEA may be used to monitor chemotherapy in patients with advanced breast cancer. In patients with nonevaluable disease, sustained increases in CEA concentrations suggest progressive disease [LOE, III; SOR, B].

BRCA1 and BRCA2 genes. According to the task force of the Cancer Genetics Studies Consortium, early breast and ovarian cancer screening are recommended for individuals with breast cancer 1, early onset (BRCA1) mutations and early breast cancer screening for those with breast cancer 2, early onset (BRCA2) mutations (382). No recommendation, however, was made for or against prophylactic surgery (e.g., mastectomy or oophorectomy). The guidelines further stated that “these surgeries are an option for mutation carriers, but evidence of benefit is lacking, and case reports have documented the occurrence of cancer following prophylactic surgery. It is recommended that individuals considering genetic testing be counselled regarding the unknown efficacy of measures to reduce risk and that care for individuals with cancer-predisposing mutations be provided whenever possible within the context of research protocols designed to evaluate clinical outcome” (382). It is important to point out that these guidelines were based on expert opinion only.

In 2003, an ASCO Panel published a detailed policy statement regarding genetic testing for cancer susceptibility (324). This statement included recommendations in the following areas: indications for genetic testing, regulation of testing, insurance reimbursement, protection from discrimination, confidentiality issues associated with genetic testing, and continuing educational challenges and special research issues surrounding genetic testing of human tissues.

According to the 2005 Consensus Panel of the 8th St Gallen Conference, treatment decisions for women with mutations in BRCA1 or BRCA2 genes “need to include consideration of bilateral mastectomy with plastic surgical reconstruction, prophylactic oophorectomy, chemoprevention and intensified surveillance” (350).

**NACB BREAST CANCER PANEL RECOMMENDATION 6:**

**BRCA1 AND BRCA2 MUTATION TESTING FOR IDENTIFYING WOMEN AT HIGH RISK OF DEVELOPING BREAST CANCER**

BRCA1 and BRCA2 mutation testing may be used for identifying women who are at high risk of developing breast or ovarian cancer in high-risk families. For those with such mutations, screening should begin at 25–30 years of age. Insufficient data exist, however, to recommend a specific surveillance/screening strategy for young women at high risk. Appropriate counselling should be given to any individual considering BRCA1/2 testing [LOE, expert opinion; SOR, B].
MULTIGENE GENE SIGNATURES

**Gene expression profiling.** Gene expression profiling uses microarray technology to measure the simultaneous expression of thousands of genes. At least 8 gene signatures have been described for predicting outcome in patients with breast cancer [for review, see ref (385)]. Although these signatures contain few genes that overlap, most give similar prognostic information (386).

In one of the first clinical microarray studies, van’t Veer et al. (387) described a 70-gene signature that correctly predicted the later appearance of distant metastasis in 65 of 78 patients with newly diagnosed lymph node–negative breast cancer patients younger than 55 years who had not received systemic treatment. Application of this signature to an independent set of 19 breast cancers resulted in only 2 incorrect classifications. This 70-gene signature was subsequently both internally (388) and externally validated (389). In both the internal and external validations studies, the prognostic impact of the gene signature was independent of the conventional prognostic factors for breast cancer.

Currently this 70-gene signature is undergoing prospective validation as part of the Microarray for Node-Negative Disease Avoids Chemotherapy (MINDACT) trial (390). The primary objective of this trial is to establish if lymph node–negative breast cancer patients with low risk of recurrence based on the above gene signature but at high risk of recurrence based on clinicopathological factors can be safely spared adjuvant chemotherapy without affecting distant metastasis-free survival.

**NACB BREAST CANCER PANEL RECOMMENDATION 7:**

**GENE EXPRESSION PROFILING, AS DETERMINED BY MICROARRAY, FOR PREDICTING OUTCOME**

None of the microarray-based gene signatures currently available should be routinely used for predicting patient outcome [LOE, III; SOR, B].

**Oncotype DX™ test.** Oncotype DX™ is a multigene assay that quantifies the likelihood of breast cancer recurrence in women with newly diagnosed, early-stage breast cancer (for review, see (391)). Rather than using microarray technology, this test uses reverse-transcript PCR to measure the expression of 21 genes (16 cancer-associated and 5 control genes). Based on the expression of these genes, a recurrence score (RS) was calculated that predicted low, intermediate, and high risk of distant metastasis for ER-positive patients treated with adjuvant tamoxifen (392). The RS was prospectively validated in an independent population of lymph node–negative ER-positive patients treated with adjuvant tamoxifen, as part of the National Surgi-

cal Adjuvant Breast and Bowel Project trial B14 (392). In this validation study, the RS was an independent predictor of patient outcome. The independent prognostic impact of the RS was later confirmed in a population-based case-control study (393). Although a low RS predicted good outcome in patients treated with adjuvant tamoxifen, a high RS was found to be associated with favorable outcome in patients treated with either neoadjuvant or adjuvant chemotherapy (394, 395). A particular advantage of this test is that it may be carried out on formal-fixed paraffin embedded tissue.

Currently, the RS is undergoing prospective validation as part of the Trial Assigning Individualized Options for Treatment (TAILORx) trial (396). In this trial, patients with intermediate RS are being randomized to receive hormonal therapy alone or hormone therapy plus chemotherapy. The aim is to establish if adjuvant chemotherapy improves survival in the group of patients with the intermediate score. Also, in this trial, patients with low RS after tamoxifen therapy will receive endocrine treatment, whereas those with high RS will be given chemotherapy and hormone therapy.

**NACB BREAST CANCER PANEL RECOMMENDATION 8:**

**ONCOTYPE DX TEST FOR PREDICTING OUTCOME**

The Oncotype DX test may be used for predicting recurrence in lymph node–negative, ER-positive patients receiving adjuvant tamoxifen. Patients predicted to have a good outcome may be able to avoid having to undergo treatment with adjuvant chemotherapy [LOE, I/II; SOR, A].

The Oncotype DX test may also be used to predict benefit from adjuvant chemotherapy (cyclophosphamide-methotrexate-5-fluorouracil or methotrexate-5-fluorouracil) in node-negative, ER-positive patients, i.e., patients with a high recurrence score appear to derive greater benefit from chemotherapy than those with low scores [LOE, III; SOR, B].

**KEY POINTS: TUMOR MARKERS IN BREAST CANCER**

The best-validated markers in breast cancer are all tissue based and include ER, PR, HER-2, uPA, and PAI-1. Assay of ER, PR, and HER-2 is now mandatory for all newly diagnosed breast cancer patients. The measurement of uPA and PAI-1, although technically and clinically validated (361–363, 366, 367), is not presently in widespread clinical use, mainly due to the requirement of a minimum amount of fresh or freshly frozen tissue. Assay of these proteins however, may be used to aid in the selection of lymph node–negative breast cancer patients who do not need adjuvant chemotherapy. Similarly, the Oncotype DX test may be used for predicting recurrence in lymph node–negative, ER-positive pa-
tients receiving adjuvant tamoxifen. Although widely used in postoperative surveillance and monitoring therapy in advanced disease, the clinical value of CA 15-3 and other serum markers has not yet been validated by a level I evidence study.

**Tumor Markers in Ovarian Cancer**

**BACKGROUND**

In the US, ovarian cancer is among the top 4 most lethal malignant diseases in women, who have a lifetime probability of developing the disease of 1 in 59 (397). Worldwide, the incidence of ovarian cancer was estimated as 204,499 cases per year with a corresponding 124,860 deaths (398).

The overall mortality of ovarian cancer is still high despite new chemotherapeutic agents, which have significantly improved the 5-year survival rate (118). The main reason for high mortality is lack of success in diagnosing ovarian cancer at an early stage, because the great majority of patients with advanced stage ovarian carcinoma die of the disease. In contrast, if ovarian cancer is detected early, 90% of those with well-differentiated disease confined to the ovary survive. Furthermore, biomarkers that can reliably predict clinical behavior and response to treatment are generally lacking. The search for tumor markers for the early detection and outcome prediction of ovarian carcinoma is therefore of profound importance and is a subject of critical importance in the study of ovarian cancer.

Although ovarian cancer is often considered to be a single disease, it is composed of several related but distinct tumor categories including surface epithelial tumors, sex-cord stromal tumors, and germ cell tumors (399). Within each category are several histological subtypes. Of these, epithelial tumors (carcinomas) are the most common and are divided, according to the International Federation of Gynecology and Obstetrics (FIGO) and WHO classifications, into 5 histologic types: serous, mucinous, endometrioid, clear cell, and transitional (400). The different types of ovarian cancers are not only histologically distinct but are characterized by different clinical behavior, tumorigenesis, and pattern of gene expression. Based on prevalence and mortality, serous ovarian carcinoma is the most important and represents the majority of all primary ovarian carcinomas (401). Therefore, unless otherwise specified, serous carcinoma is what is generally thought of as “ovarian cancer.”

The search for more effective biomarkers depends on a better understanding of the pathogenesis of ovarian cancer, i.e., the molecular events in its development. Based on a review of recent clinicopathological and molecular studies, a model for the development of ovarian carcinomas has been proposed (402). In this model, surface epithelial tumors are divided into 2 broad categories designated type I and type II tumors, which correspond to 2 main pathways of tumorigenesis.

Type I tumors tend to be low-grade neoplasms that arise in a stepwise fashion from borderline tumors, whereas type II tumors are high-grade neoplasms for which morphologically recognizable precursor lesions have not been identified, so-called de novo development. Because serous tumors are the most common surface epithelial tumors, low-grade serous carcinoma is the prototypic type I tumor, and high-grade serous carcinoma is the prototypic type II tumor.

In addition to low-grade serous carcinomas, type I tumors are composed of mucinous carcinomas, endometrioid carcinomas, malignant Brenner tumors, and clear cell carcinomas. Type I tumors are associated with distinct molecular changes that are rarely found in type II tumors, such as BRAF39 and KRAS mutations for serous tumors, KRAS mutations for mucinous tumors, and β-catenin and PTEN mutations and MSI for endometrioid tumors.

Type II tumors include high-grade serous carcinoma, malignant mixed mesodermal tumors (carcinosarcoma), and undifferentiated carcinoma. There are very limited data on the molecular alterations associated with type II tumors, except frequent p53 mutations in high-grade serous carcinomas and malignant mixed mesodermal tumors (carcinosarcomas). This model of carcinogenesis provides a molecular platform for the discovery of new ovarian cancer markers.

To prepare these guidelines, the literature relevant to the use of tumor markers in ovarian cancer was reviewed. Particular attention was given to reviews including systematic reviews, prospective randomized trials that included the use of markers, and guidelines issued by expert panels. Where possible, the consensus recommendations of the NACB Panel were based on available evidence, i.e., were evidence-based.

**CURRENTLY AVAILABLE MARKERS FOR OVARIAN CANCER**

The most widely studied ovarian cancer body fluid- and tissue-based tumor markers for ovarian cancer are listed in Table 15, which also summarizes the phase of

39 BRAF, v-raf murine sarcoma viral oncogene homolog B1; KRAS, v-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog; PTEN, phosphatase and tensin homolog.
development of each marker and LOE for its clinical use. The LOE grading system is based on a previous report describing the framework to evaluate clinical utility of tumor markers (120). The following discussion will focus mainly on CA125, which is the most widely investigated marker in ovarian cancer.

**TUMOR MARKERS IN OVARIAN CANCER: NACB RECOMMENDATIONS**

Several organizations, including the EGTM (403, 404), the American College of Physicians (405), the European Society for Medical Oncology (406) and the NCCN (407) have developed guidelines for the use of CA125 as a tumor marker for ovarian cancer. In addition, an NIH Consensus Conference on screening, prevention, diagnosis, and treatment of ovarian cancer was held in 1994 (408). Recommendations from these groups are summarized in Table 16. Table 16 also includes previous recommendations from the NACB as well as current recommendations based on the information below and other established guidelines.

**CA125**

In 1981, Bast et al. identified the CA125 antigen with the development of the OC 125 murine monoclonal antibody against cell line OVCA 433, which was de-

* ESMO, European Society of Clinical Oncology.

** LOE (120), level 1, evidence from a single, high-powered, prospective, controlled study that is specifically designed to test the marker, or evidence from a meta-analysis, pooled analysis or overview of level II or III studies; level II, evidence from a study in which marker data are determined in relationship to prospective therapeutic trial that is performed to test therapeutic hypothesis but not specifically designed to test marker utility; level III, evidence from large prospective studies; level IV, evidence from small retrospective studies; level V, evidence from small pilot studies.

*** SOR (520), A, high (further research is very unlikely to change the panel’s confidence in the estimate of effect); B, moderate (further research is likely to have an important impact on the panel’s confidence in the estimate of effect and is likely to change the estimate); C, low (further research is very likely to have an important effect on the panel’s confidence in the estimate of effect and is likely to change the estimate); D, very low (any estimate of effect is very uncertain).
rived from a patient with ovarian serous carcinoma (409). The CA125 molecule has since been cloned by use of a partial cDNA sequence originating from the peptide core of the molecule identified (410). This new mucin molecule has been designated CA125/MUC16 [mucin 16, cell surface associated (MUC16) gene] and consists of a 156–amino-acid tandem-repeat region in the N-terminus and a possible transmembrane region and tyrosine phosphorylation site in the C-terminus.

The first immunoassay for CA125, commercialized in 1983, used the OC 125 antibody for both capture and detection (411, 412). A second-generation assay (CA125 II) was subsequently developed, incorporating M11 and OC 125 antibodies, which have distinct nonoverlapping epitopes. Assays for CA125 have since been adapted to automated platforms, and although the majority of manufacturers quote a similar reference interval, concentrations of CA125 may vary among manufacturers owing to differences in calibration, assay design, and reagent specificities. The lack of an International Standard for CA125 hampers progress in improving between-method comparability, and the clinical and laboratory communities should work toward producing and adopting such a standard. For the present, values from different methods are not interchangeable, and patients who are serially monitored should be rebaselined if there is a change in methodology (413). Manufacturers should specify the standard preparation against which their method is calibrated, and laboratories should indicate the CA125 method used on their clinical reports.

The cutoff of 35 kU/L for the CA125 and CA125II assays was determined from the distribution of values in healthy individuals so as to include 99% of normals (414). Values tend to decline with menopause and aging (415). It has recently been reported that CA125 concentrations vary 20%–50% by race in postmenopausal women, with concentrations in African and Asian women lower than in white women (415). Menstrual cycle variations can also be found (412). Increased values may be found in 1%–2% of normal healthy individuals, 5% of those with benign diseases, and 28% of those with nongynecologic cancers (15, 411, 412).

It is recommended that analysis be performed shortly after prompt centrifugation of the specimen and separation of serum from the clot, and that specimens be stored at either 4 °C (1–5 days) or −20 °C (2 weeks–3 months) in the short term, or −70 °C in the long term to ensure stability (15). Plasma is an acceptable specimen type for some assays, where indicated by the manufacturer. As in other immunoassays, assay interferences may be observed if heterophilic antibodies are present in the serum, particularly following therapeutic or diagnostic use of monoclonal antibodies.

**SCREENING/EARLY DETECTION**

In women with epithelial ovarian cancer, 80% have CA125 levels >35 kU/L, with elevations of 50%–60% in clinically detected stage I disease, 90% in stage II, and >90% in stages III and IV (412, 416). Concentrations correlate with tumor burden and stage. Owing to the lack of sensitivity and specificity for a single determination of the marker, CA125 is not recommended for use in screening asymptomatic women by the NACB Panel or by other authoritative organizations (15, 403, 405–408). An NIH Consensus Development Panel has concluded that evidence is not yet available to indicate that either CA125 or transvaginal ultrasonography effectively reduce mortality from ovarian cancer (408). However, the same panel did recommend annual CA125 determinations, in addition to pelvic and ultrasound examinations, in women with a history of hereditary ovarian cancer who have an estimated lifetime risk of 40%, because early intervention may be beneficial.

A number of approaches have been proposed to improve the specificity of CA125 for early detection, because very high specificity (99.7%) is needed to achieve an acceptable positive predictive value of 10% with a prevalence of disease of 40 per 100 000 in women older than 50 years (417). Strategies have included sequential or 2-stage strategies combining CA125 with ultrasound, longitudinal measurements of CA125, and measurement of CA125 in combination with other markers such as OVX1, macrophage colony-stimulating factor, or other new biomarkers discovered using proteomic profiling approaches (411, 417–419). To evaluate the potential role for CA125 in screening for ovarian cancer in asymptomatic populations, 2 major prospective randomized trials are currently in progress in the US (420) and the United Kingdom (421). In total 200 000 women will be randomized to either screening with ultrasound, screening with CA125 plus ultrasound, or no screening. The studies are adequately powered to detect a significant improvement in sur-
vival among women screened with serial CA125 measurements and transvaginal sonography.

**NACB OVARIAN CANCER PANEL RECOMMENDATION 2: CA125 IN SCREENING**

CA125 is not recommended for screening asymptomatic women [LOE, III; SOR, B].

CA125 is recommended, together with transvaginal ultrasound, for early detection of ovarian cancer in women with hereditary syndromes because early intervention may be beneficial in these women [LOE, III; SOR, B].

**DISCRIMINATION OF PELVIC MASSES**

In contrast to its use in early detection, CA125 is more widely accepted as an adjunct in distinguishing benign from malignant disease in women, particularly in postmenopausal women presenting with ovarian masses (407, 408, 422), facilitating triage for operations by optimally qualified surgeons. Benign conditions resulting in increased CA125 levels may be a confounding factor in premenopausal women. In the United Kingdom CA125 measurement is an integral part of the RMI (risk of malignancy index), which forms the basis of patient pathway guidelines for the management of pelvic masses and/or adnexal cysts (423). The RMI is calculated as a product of CA125 concentration multiplied by menopausal status (1 for premenopausal and 3 for postmenopausal) multiplied by ultrasound score (0, 1, or 3 depending on ultrasound features). A cutoff of 200 or 250 is frequently used, with patients with scores above this referred to specialist gynecology–oncology teams. Sensitivities of 71%–78% and specificities of 75%–94% have been reported in other studies (414). Increased concentrations of CA125 >95 kU/L in postmenopausal women can discriminate malignant from benign pelvic masses with a positive predictive value of 95% (411). Therefore, based on current evidence, CA125 is recommended as an adjunct in distinguishing benign from malignant pelvic masses, particularly in postmenopausal women. When there is a suspicion of germ cell tumor, particularly in women younger than 40 years or in older women where scan features suggest a germ cell tumor, AFP and hCG are also important markers for triage, as for testicular germ cell tumors.

**NACB OVARIAN CANCER PANEL RECOMMENDATION 3: CA125 IN DISCRIMINATION OF PELVIC MASSES**

CA125 is recommended as an adjunct in distinguishing benign from malignant suspicious pelvic masses, particularly in postmenopausal women [LOE, III/IV; SOR, A].

**MONITORING TREATMENT**

Serial measurement of CA125 may also play a role in monitoring response to chemotherapy. Declining CA125 concentrations appear to correlate with treatment response even when disease is not detectable by either palpation or imaging. In a meta-analysis, serial CA125 concentrations in 89% of 531 patients correlated with clinical outcome of disease (424–426). There is general consensus among current guidelines in recommending that CA125 be used to monitor therapeutic response, but there is no consensus as to how best to define a CA125-based response (404, 427, 428). A response has been defined as a reduction of 50% or more in pretreatment CA125 level that is maintained for at least 28 days (428–431). The pretreatment sample must be at least twice the upper limit of the reference range, which means that patients with pretreatment concentrations between the upper limit and twice the upper limit are nonassessable by this criterion. The first sample is recommended within 2 weeks before treatment, with subsequent samples at 2–4 weeks during treatment and at intervals of 2–3 weeks during follow-up. The same assay method is required throughout, and patients who received immunotherapy (mouse antibodies) cannot be evaluated.

In addition to monitoring initial chemotherapeutic regimens, CA125 measurements may be useful in monitoring salvage therapy, because a doubling of values is associated with disease progression and treatment failure in more than 90% of cases (411). However, disease progression may also occur without an increase in CA125, and therefore the presence of tumor should also be assessed by physical examination and imaging (15). Tuxen et al. (427) suggested that interpretation of changes in serial CA125 levels should be based on a statistical estimation that takes account both the analytical variation of the method used and of the normal background intrapatient biological variation of the marker (432, 433). The theoretical background for this statistical procedure has recently been reviewed in detail (434). Serial measurement of CA125 to aid in monitoring response to therapy is a second FDA-indicated use for the marker. Trials currently in progress, including the UK Medical Research Council OV05 trial, have been designed to evaluate the benefit of early chemotherapy for recurrent ovarian cancer, based on a raised CA125 level alone, vs chemotherapy based on conventional clinical indicators (435). Pending results of these trials, practice is likely to vary.

**NACB OVARIAN CANCER PANEL RECOMMENDATION 4: CA125 IN MONITORING TREATMENT**

CA125 measurements may be used to monitor response to chemotherapeutic response. The first
CA125 MEASUREMENT POSTOPERATIVELY: SECOND-LOOK OPERATION

Early studies on CA125 indicated that it was useful postoperatively in predicting the likelihood that tumor would be found at a second-look operation, and CA125 assays were initially cleared by the FDA for this indication (412, 424). Elevations of CA125 > 35 kU/L after debulking surgery and chemotherapy indicate that residual disease is likely (>95% accuracy) and that chemotherapy will be required (436). Second-look laparotomy is now considered to be controversial and suggested only for patients enrolled in clinical trials or in situations in which surgical findings would alter clinical management. Monitoring with CA125 testing in women with increased preoperative CA125 concentrations, along with a routine history and physical and rectovaginal pelvic examination, has been advocated instead of surgery for asymptomatic women after primary therapy (408).

CA125 MEASUREMENT POSTOPERATIVELY: DETECTION OF RECURRENCE

Increased, rising, or doubling CA125 concentrations predict relapse. However, it should be noted that postoperative CA125 levels below the cutoff concentration do not necessarily exclude disease presence.

The Gynecologic Cancer Intergroup (GCIG) is an organization consisting of representatives from thirteen international groups performing clinical trials in gynecologic cancer (437). The GCIG has defined criteria progression using serial CA125 measurements (431) as:

- CA125 concentrations $\geq$ twice the upper limit of normal on 2 occasions in patients with increased CA125 levels pretreatment that normalize, or patients with CA125 in the reference range or
- CA125 concentrations $\geq$ the nadir value on 2 occasions in patients with increased CA125 levels pretreatment that do not normalize.

The 2 measurements must be at least 1 week apart (431).

Although monitoring intervals are as yet undefined, current practice suggests following patients every 2 to 4 months for 2 years and then less frequently (407). Elevations in CA125 can precede clinical or radiological evidence of recurrence, with a median time of 2 to 6 months, although there is no evidence to date that initiating salvage chemotherapy before clinical recurrence improves survival (436). Early detection of recurrent disease, however, permits the timely evaluation of the multiple drugs available for salvage therapy. Because only a fraction of patients will respond to any single drug and reliable predictive tests are not yet available, chemotherapeutic agents are generally used individually and sequentially to identify those drugs that are active against a particular patient’s cancer. Given the modest difference between time to recurrence and overall survival, early detection of recurrence provides time in which to identify effective palliative therapy. Therefore, measurement of CA125 at follow-up visits is recommended if values were initially increased. Low preoperative concentrations do not exclude the possibility that CA125 concentrations may increase above the cutoff before clinical relapse, and progressive increases in CA125 within the reference interval may be predictive of recurrence (438).

NACB OVARIAN CANCER PANEL RECOMMENDATION 5:
CA125 IN MONITORING PATIENTS AFTER THERAPY

Measurement of CA125 at follow-up visits is recommended if values were initially increased. Although monitoring intervals are as yet undefined, current practice suggests following patients every 2 to 4 months for 2 years and then less frequently [LOE, III; SOR, B].

PROGNOSIS

CA125 is recommended during primary therapy as a potential prognostic marker because CA125 concentrations, both preoperative and postoperative, may be of prognostic significance (439–442). After primary surgery and chemotherapy, declines in CA125 concentrations during chemotherapy have generally been observed to be independent prognostic factors, and in some studies the most important indicator. Persistent elevations indicate a poor prognosis. In patients who had a preoperative CA125 concentration $>65$ kU/L, the 5-year survival rates were significantly lower and conferred a 6.37-fold risk of death compared to patients who had values $<65$ kU/L (412, 426). In addition to the measured level, the half-life of the CA125 marker indicates prognosis after chemotherapy. A half-life of $<20$ days was associated with significantly improved survival (28 months vs 19 months) compared to $>20$ days (411, 443). Improved survival also correlates with normalization of CA125 after 3 cycles of combination chemotherapy. These findings have been supported by a recent study suggesting that CA125...
The Kallikrein family. Kallikreins are a subgroup of the serine protease enzyme family that play an important role in the progression and metastasis of human cancers (445). Kallikreins 4, 5, 6, 7, 8, 9, 10, 11, 13, 14, and 15 in ovarian cancer have been shown to have value in detection, diagnosis, prognosis prediction, and monitoring of ovarian cancer (446–463). Kallikrein 4, for example, is expressed in the majority of serous carcinomas but rarely in normal ovarian surface epithelium (449, 450). Kallikrein 4 expression is associated with higher clinical stage and tumor grade in ovarian cancer: a univariate survival analysis revealed that patients with ovarian tumors positive for kallikrein 4 expression had an increased risk for relapse and death (450). Similarly, kallikrein 5 has been suggested to be a useful independent prognostic indicator in patients with stage I and II disease (451). Assessment of kallikrein 5 expression could help oncologists determine those patients at higher risk of relapse. Kallikrein 7 expression in ovarian cancer tissue is associated with poorer prognosis of ovarian cancer patients, especially those with lower grade disease and those who have been optimally debulked (464). In contrast, kallikrein 8 (neuropsin or ovasin) (452), kallikrein 9 (465), and kallikrein 11 (462) are favorable prognostic markers in ovarian cancer. Patients with higher kallikrein 8 expression in their tumors have lower-grade disease, lower residual tumor, longer survival, and low rate of recurrence. In a multivariate analysis, higher kallikrein 8 expression was significantly associated with longer disease-free survival. As well as their roles as tissue markers, kallikrein 6, 10, and 11 can be detected in serum, and are potential serological markers of the disease (446, 448, 466). A recent comprehensive and parallel analysis of different secreted kallikreins in ovarian cancer has demonstrated that kallikreins 6, 7, 8, and 10 are the 4 most specific secreted kallikreins in ovarian cancer effusions (467). These kallikreins may have clinical applications in the differential diagnosis of ovarian carcinoma from benign controls and other cancer types.

Osteopontin. Osteopontin was first identified by a cDNA microarray approach used to identify upregulated genes in ovarian cancer cells, and osteopontin has been found to be a potential diagnostic biomarker for ovarian cancer (468). In the original report, osteopontin expression was higher in invasive ovarian cancer than in borderline ovarian tumors, benign ovarian tumors, and normal ovarian surface epithelium (468). Plasma levels of osteopontin were significantly higher in patients with epithelial ovarian cancer compared to healthy controls, patients with benign ovarian disease, and patients with other gynecologic cancers. In a more recent report (469), osteopontin has been shown to be less sensitive than CA125 in predicting clinical response to therapy. However, osteopontin increased earlier than CA125 in 90% of the study patients who developed recurrent disease, indicating that osteopontin may be a clinically useful adjunct to CA125 in detecting recurrent ovarian cancer.

Prostasin. Using gene expression profiling by cDNA microarrays, Mok et al. have identified an overexpressed gene called prostasin that produces a secretory product (470). Prostasin [alias for PRSS8 (protease, serine, 8)] was originally isolated from human seminal fluid and its highest levels are found in the prostate gland (471). Prostasin was detected more strongly in ovarian carcinoma than in normal ovarian tissue. The mean level of serum prostasin was 13.7 μg/mL in patients with ovarian cancer and 7.5 μg/mL in control subjects. In a series of patients with nonmucinous ovarian carcinoma, the combination of prostasin and CA125 gave a sensitivity of 92% and a specificity of 94% for detecting ovarian cancer. Although the above finding is promising, prostasin should be investigated further as a screening or tumor marker, both alone and in combination with CA125.

Tissue polypeptide antigen. Tissue polypeptide antigen (TPA) is a single-chain polypeptide that may be made up of proteolytic fragments of the cytokeratins (472). Production of TPA may be associated with rapid cell turnover, and increased TPA levels in serum have been reported in patients suffering from cancers and other disease (473). In ovarian cancers of serous and mucinous type, TPA levels correlate with FIGO stage; 33%–
50% of patients with stage I–II disease, and 88%–96% of patients with stage III–IV disease presented with increased serum TPA. Serial TPA measurements correlated with the clinical course of ovarian cancer in 42%–79% of the matched events. These findings suggest that TPA may be a potential marker for following ovarian cancer in patients.

**Lysophosphatidic acid.** Lysophosphatidic acid (LPA) was first identified in ascites of ovarian cancer patients and has since been demonstrated to play a biological role in ovarian cancer cell growth (474–477). In a preliminary study in a small number of patients (474), plasma LPA concentrations were increased in 90% of patients with stage I disease and 100% of patients with advanced and recurrent disease compared to controls without apparent diseases, although 80% of women with other gynecologic cancers also had increased levels. CA125 concentrations appeared to complement LPA levels.

**Tumor-associated trypsin inhibitor.** Tumor-associated trypsin inhibitor (TATI) was first identified from the urine of patients with ovarian cancer (478). The amino acid sequence and biochemical properties of TATI are identical to those of pancreatic secretory trypsin inhibitor (479). Increased serum and urinary concentrations of TATI are frequently observed in postoperative patients, in severe inflammatory diseases, and in various types of cancer, especially gynecological and pancreatic cancer (473). Increased concentrations of TATI can be observed in ovarian cancers, especially the mucinous types. The increased serum levels of TATI appear to correlate with higher stages of disease. In one report, the sensitivity was only 8% in patients with stage I-II and 62% of patients with stage III-IV disease (480). Several reports suggest that TATI is not a good marker for monitoring disease during therapy, because TATI has a lower sensitivity for residual tumor than CA125, and <50% of the matched clinical events are observed to correlate serum levels of TATI.

**Carcinoembryonic antigen.** CEA is an oncofetal antigen (473), and increased serum levels of CEA are frequently found in a variety of benign diseases and cancers, including ovarian carcinoma. The frequency of increased concentration in ovarian carcinoma varies with the histological type and disease stage, generally being higher in patients with mucinous ovarian cancers and with metastatic disease. The sensitivity of CEA as a marker to detect ovarian cancer is approximately 25%, and the positive predictive value of an increased CEA concentration is only 14% (473). Although CEA is not a marker for early diagnosis owing to its low sensitivity, CEA can be useful in determining treatment response in ovarian cancer patients.

**Cancer-associated serum antigen.** Cancer-associated serum antigen (CASA) was initially defined by a monoclonal antibody that bound to an epitope on the polymorphic epithelial mucin (481). Increased CASA levels in serum were found in individuals in the later stage of pregnancy, in the elderly, in smokers, and in patients with cancers. CASA is expressed in all histological types of ovarian cancer and appears to have a sensitivity of 46%–73% in patients with ovarian cancer (473). Only a few studies have indicated that CASA is a potentially useful marker in monitoring ovarian cancer. Ward et al. reported that inclusion of CASA in a diagnostic tumor panel might improve the detection of residual disease by increasing the sensitivity from 33% to 62% and the negative predictive value from 66% to 78% (482, 483). One study has demonstrated that CASA can detect more cases with small volume disease than CA125, and that 50% of patients with microscopic disease are detected by CASA alone (473). Another study has shown that the prognostic value of postoperative serum CASA level is superior to CA125 and other parameters including residual disease, histological type, tumor grade, and the cisplatin-based chemotherapy (484).

**PAI-1 and PAI-2.** Fibrinolytic markers include PAI-1 and PAI-2, for which diagnostic and prognostic values have recently been reported in ovarian cancer (485). In this pilot study, PAI-1 appeared to be a poor prognostic factor (486), because plasma levels of PAI-1 are significantly higher in patients with ovarian cancer, and their levels correlate with the diseases at higher clinical stages. Whether PAI-1 can be used clinically for screening and/or monitoring ovarian cancer awaits further studies, including correlation with clinical treatment events and comparison with CA125. In contrast, expression of PAI-2 in tumors has been shown to be a favorable prognostic factor in ovarian cancer patients (485).

**Interleukin-6.** High levels of interleukin-6 have been detected in the serum and ascites of ovarian cancer patients (487). Interleukin-6 correlates with tumor burden, clinical disease status, and survival time of patients with ovarian cancer, implying that this marker may be useful in diagnosis. Based on a multivariate analysis, investigators have found serum levels of interleukin-6 to be of prognostic value, but less sensitive than CA125 (488, 489).

**Human chorionic gonadotropin.** hCG normally is produced by the trophoblast, and clinically has been used as a serum or urine marker for pregnancy and gestational trophoblastic disease (490). Ectopic hCG production, however, has been detected in a variety of human cancers. Recent studies have demonstrated that
the immunoreactivity of total hCG in serum and urine provides a strong independent prognostic factor in ovarian carcinoma, and its prognostic value is similar to that of grade and stage (491, 492). When serum hCG is normal, the 5-year survival rate can be as high as 80%, but it is only 22% when hCG is increased (491). In patients with stage III or IV and minimal residual disease, the 5-year survival is 75% if hCG is not detectable compared to 0% if hCG is increased. Similarly, hCG β core fragment (hCGβcf) can be detected in urine in 84% of ovarian cancer patients (492). The incidence of positive urinary hCGβcf correlates with disease progression, with elevations observed in a higher proportion of patients in advanced clinical stages. Although the availability of this marker before surgery could facilitate selection of treatment modalities, the clinical application of hCG and hCGβ for screening and diagnosis is limited. Since several different types of tumors can produce hCG±hCGβ, and only a small proportion of ovarian tumors express these, detection of serum hCG±hCGβ or urinary hCGβcf will not provide a specific or sensitive tool for screening or diagnosis in ovarian cancer.

HER-2/neu gene. The c-erbB-2 oncogene expresses a transmembrane protein, p185, with intrinsic tyrosine kinase activity, also known as HER2/neu. Amplification of Her2/neu has been found in several human cancers, including ovarian carcinoma. In ovarian cancer, 9% to 38% of patients have increased levels of p105, the shed extracellular domain of the HER-2/neu protein (493–495). According to one report, measurement of Her2/neu alone or in combination with CA125 is not useful for differentiating benign from malignant ovarian tumors (495). However, elevation of p105 in serum or the overexpression immunohistochemically of Her2/neu in tumors has correlated with an aggressive tumor type, advanced clinical stages, and poor clinical outcome (496). Screening for increased p105 levels might therefore make it possible to identify a subset of high-risk patients (494). Furthermore, the test could be potentially useful for detecting recurrent disease.

AKT2 gene. The v-akt murine thymoma viral oncogene homolog 2 (AKT2) gene is one of the human homologs of v-akt, the transduced oncogene of the AKT8 virus, which experimentally induces lymphomas in mice. AKT2, which codes for a serine-threonine protein kinase, is activated by growth factors and other oncogenes such as v-Ha-ras and v-src through phosphatidylinositol 3-kinase in human ovarian cancer cells (497, 498). Studies have shown that the AKT2 gene is amplified and overexpressed in approximately 12–36% of ovarian carcinomas (499–501). In contrast, AKT2 alteration was not detected in 24 benign or borderline tumors.

Ovarian cancer patients with AKT2 alterations appear to have a poor prognosis. Amplification of AKT2 is more frequently found in histologically high-grade tumors or tumors at advanced stages (III or IV), suggesting that AKT2 gene overexpression, like c-erbB-2, may be associated with tumor aggressiveness (500).

Mitogen-activated protein kinase. Activation of mitogen-activated protein kinase occurs in response to various growth stimuliating signals and as a result of activating mutations of the upstream regulators, KRAS and BRAF, which can be found in many types of human cancer. Activation of mitogen-activated protein kinase activates downstream cellular targets (502, 503) including a variety of cellular and nuclear proteins. Two studies have reported that expression of active mitogen-activated protein kinase in ovarian cancer tissue or ascites cells correlates with better prognosis in the advanced stage ovarian cancer (504, 505).

Inhibin. Inhibin is a glycoprotein and member of the transforming growth factor β family. Inhibins A and B are heterodimers consisting of identical α-subunits and either βA or βB subunits linked with disulfide bonds (506–508). Inhibin is primarily produced by the gonads and functions as a regulator of follicle-stimulating hormone secretion. Inhibin is associated with granulosa cell tumors and mucinous carcinomas as opposed to CA125, which is associated with serous, endometrioid, and undifferentiated tumors. In addition the α subunit may function as an ovarian tumor suppressor. Using a total inhibin ELISA in combination with CA125 has been shown to detect the majority of ovarian cancer types with 95% sensitivity and specificity (507).

RSF-1 gene. The clinical significance of the remodeling and spacing factor 1 (RSF-1) gene in ovarian cancer was first demonstrated by analyzing a new amplified chromosomal region, 11q13.5, in the ovarian cancer genome by use of digital karyotyping. The RSF-1 gene belongs to the SWI/SNF chromatin remodelling gene family and Rsf-1 protein partners with hSNF2h to form the chromatin remodelling complex, RSF (remodelling and spacing factor) (509). It has been shown that Rsf-1 participates in chromatin remodelling (509) and transcriptional regulation (510, 511). Previous studies have demonstrated that RSF-1 amplification and overexpression are associated with the most aggressive type of ovarian cancer, and patients with RSF-1 gene amplification in their carcinomas had a significantly shorter overall survival (512–514). Further multinstitutional studies are required to validate the clinical significance of RSF-1 gene amplification for future clinical practice.
NAC-1 gene. The genes within the BTB/POZ family participate in several cellular functions including proliferation, apoptosis, transcription control, and cell morphology maintenance (515). The roles of BTB/POZ proteins in human cancer have been recently revealed as several of BTB/POZ proteins such as BCL-6 are involved in cancer development. Based on analyzing gene expression levels in all 130 deduced human BTB/POZ genes using the serial analysis of gene expression data, Nakayama et al. have recently identified NAC-1 as a carcinoma-associated BTB/POZ gene (516). NAC-1 is a transcription repressor and is involved in self-renewal and maintaining pluripotency of embryonic stem cells (517). In ovarian carcinomas, NAC-1 is significantly over expressed in high-grade carcinoma but not in borderline tumors or benign cystadenomas. The levels of NAC-1 expression correlate with tumor recurrence in ovarian serous carcinomas and intense NAC-1 immunoreactivity in primary ovarian tumors predicts early recurrence (516, 518). As the NAC-1 specific antibody is available to evaluate NAC-1 protein levels in archival paraffin sections, the marker alone or in combination with other biomarkers may hold promise for prognosis and prediction in ovarian carcinoma patients.

All other markers are either in the evaluation phase or in the research/discovery phase, therefore the NACB Panel does not recommend these biomarkers for clinical use in ovarian cancer.

Author Contributions: All authors confirmed they have contributed to the intellectual content of this paper and have met the following 3 requirements: (a) significant contributions to the conception and design, acquisition of data, or analysis and interpretation of data; (b) drafting or revising the article for intellectual content; and (c) final approval of the published article.

Authors’ Disclosures of Potential Conflicts of Interest: Upon manuscript submission, all authors completed the Disclosures of Potential Conflict of Interest form. Potential conflicts of interest:

Role of Sponsor: The funding organizations played no role in the design of study, choice of enrolled patients, review and interpretation of data, or preparation or approval of manuscript.

Acknowledgments: We would like to thank the numerous scientists and clinicians who have contributed to this undertaking, Hassima Omar Ali for her excellent assistance, Dr. David Bruns and Dr. Nader Ralif for agreeing to consider publishing these guidelines in Clinical Chemistry, and of course the National Academy of Clinical Biochemistry and the American Association of Clinical Chemistry for their much appreciated support and encouragement.
